APIC TEXT OF INFECTION CONTROL AND EPIDEMIOLOGY

Xenotransplantation

Author(s): David K.C. Cooper, MD, PhD
Thomas E. Starzl Transplantation Institute

Published: October 3, 2014

Abstract

Xenotransplantation is the transplantation of organs, tissues, or cells between different species (e.g., pig to human). It offers great potential in resolving the inadequate number of available human organs and cells for clinical transplantation. For a number of physiologic and logistic reasons, the pig is being investigated as a source of organs and cells for this purpose. There are several immunologic barriers that need to be overcome; these are in part related to the presence of natural antipig antibodies in humans that develop during infancy. These include hyperacute and acute humoral rejection, as well as the development of a thrombotic microangiopathy in the graft that may be associated with a consumptive coagulopathy in the recipient.

The most successful approach to overcoming these barriers is by genetically engineering the pig to provide it with resistance to the human humoral and cellular immune responses. Organs and cells from pigs that (1) do not express the important antigen Galα1,3Ga l (the major target for human antipig antibodies) and/or (2) express a human complement-regulatory protein (e.g., CD46, CD55) do not exhibit hyperacute rejection. Pigs that express a human antithrombotic gene (e.g., thrombomodulin, endothelial protein C receptor, or CD39) are also now available. It is hoped that a combination of these genetic modifications will offer protection against the development of thrombotic microangiopathy. Most progress has been made with pig islet transplantation in immunosuppressed, diabetic nonhuman primates, where normoglycemia has been maintained for periods in excess of 1 year without the need for exogenous insulin.

The physiologic, safety, and regulatory aspects of xenotransplantation are briefly reviewed. As the potential benefits of xenotransplantation are so considerable, extending to many conditions for which transplantation is not currently undertaken, it is well worth persisting in attempts to overcome the immunologic barriers that remain.

Key Words

- Antibody, anti-gal
- Infection
- Physiology
- Pig
- Rejection
- Xenotransplantation

Abbreviations

- AHXR, acute humoral xenograft rejection
- Gal, galactose-1,3-galactose
- GTKO, 1,3-galactosyltransferase gene-knockout
- NeuGc, N-glycolylneuraminic acid
- TM, thrombotic microangiopathy

Key Concepts

- The increasing shortage of human organs for transplantation has created renewed interest in the potential use of animal organs for this purpose.[1]
- Cross-species transplantation is known as "xenotransplantation."
- The pig has been identified as the most likely source of organs and cells for transplantation into humans. Although there are many good logistic reasons for this choice (Table 69-1), there are a number of immunologic, and possibly physiologic, barriers that need to be overcome for xenotransplantation to become clinically successful.
- The potential risk of transfer of an infectious organism from the pig organ to the human recipient and, perhaps more importantly, from the recipient to other members of the community has to be considered.

Table 69-1 The Advantages and Disadvantages of the Pig as a Potential Source of Organs and Cells for Humans, in Comparison with Those of the Baboon in this Role

	Pig	Baboon
Availability	Unlimited	Limited
Breeding potential	Good	Poor
Period to reproductive maturity	4–8 months	3–5 years
Length of pregnancy	114 ± 2 days	173–193 days
Number of offspring	5–12	1–2

Growth	Rapid (adult human size within 6 months)*	Slow (9 years to reach maximum size)
Size of adult organs	Adequate	Inadequate**
Cost of maintenance	Significantly lower	High
Anatomical similarity to humans	Moderately close	Close
Physiological similarity to humans	Moderately close	Close
Relationship of immune system to humans	Distant	Close
Knowledge of tissue typing	Considerable (in selected herds)	Limited
Necessity for blood type compatibility with humans	Probably important	Important
Experience with genetic engineering	Considerable	None
Risk of transfer of infection (xenozoonosis)	Low	High
Availability of specific pathogen-free animals	Yes	No
Public opinion	More in favor	Mixed

*Breeds of miniature swine are approximately 50 percent of the weight of domestic pigs at birth and sexual maturity and reach a maximum weight of approximately 30 percent of standard breeds.
**The size of certain organs (e.g., the heart) would be inadequate for transplantation into adult humans.

Background

In the United States alone, more than 100,000 patients waited for an organ transplant in 2013, yet the number of organs that are likely to become available in the current year is approximately 30,000.[2]

Therefore, patients awaiting a kidney transplant will have to continue with dialysis for a longer period of time, during which their physical condition may deteriorate, making them less likely to survive or benefit from the transplant. Patients awaiting organs for which there is no life-support system, such as the liver, may die if an organ does not become available. Even though there are systems, such as left ventricular assist devices, that may provide support for a patient with end-stage cardiac failure for months or even years, these can still be associated with major complications and are less than ideal.

In addition, there are many patients who might benefit from the transplantation of pig cells that could cure a medical condition. A good example of this is diabetes, in which pig pancreatic islets would provide insulin to control the glycemic state of the patient.[3]There are an estimated 1.5 million individuals with type 1 diabetes (and 20 million with type 2 diabetes) in the United States alone, and therefore the number of patients who might benefit from porcine cellular transplants is considerable.

Although there have been encouraging results with the allotransplantation of islets from deceased human donors,[4]this source will never be sufficient to provide therapy for the millions of patients with this

disease. Porcine insulin, which differs in structure by only one amino acid from human insulin, was used clinically for many years, and therefore its efficacy is proven. If porcine islets could be transplanted successfully without the need for excessive immunosuppressive therapy, this might provide a successful means of maintaining normoglycemia in diabetic patients.

Xenotransplantation is not a new phenomenon. During the past 100 years, there have been several attempts at xenotransplantation in human patients, usually with organs from nonhuman primates, none of which were considered successful.[5]The most notable was a series of chimpanzee kidney transplants in patients with renal failure carried out by Keith Reemtsma at Tulane University in the early 1960s. Although the majority of his patients lived for only a matter of weeks, one led an active life for 9 months until she died suddenly from what was believed to be an electrolyte disturbance—but not from rejection.

A number of pig organ transplants have been carried out in humans, but these have been uniformly unsuccessful.[5]In recent years, however, the ability to genetically modify pigs to provide their organs and tissues with some protection from the human immune response has resulted in a steady improvement in the experimental results; however, further research and experimentation is needed before undertaking clinical trials.[3,6,7]

IMMUNOLOGIC RESPONSES TO PIG ORGAN AND CELL TRANSPLANTS

Organ Xenotransplantation

When a pig organ is transplanted into a human or nonhuman primate, there is an immediate immune response, known as "hyperacute rejection" (Figure 69-1A).[8]This takes place within minutes or hours of the transplant and is related to binding of primate natural (preexisting) antipig antibodies to the graft vascular endothelial cells. Antibody deposition initiates complement-mediated injury of the endothelial lining, resulting in thrombosis, interstitial hemorrhage, and edema that disrupts graft function.

Figure 69-1.

Summary of the known immunologic barriers to pig-to-primate organ transplantation. (From Zhu X, Dor FJMF, Cooper DKC. Pig-to-non-human primate heart transplantation: immunologic progress over 20 years. *J Heart Lung Transplant* 2007;26:210–218, with permission).

View Image

The most important antibodies directed against pig tissues bind to galactose-*α*1,3-galactose (Gal).[9,10]Gal is found on the surface of all pig vascular endothelial cells and some other tissues,[11]and is also present in all other mammals, with the exception of humans and Old World nonhuman primates (e.g., great apes, baboons, Old World monkeys).[12]These primate species lost expression of Gal several million years ago, and the absence of Gal resulted in primates making antibodies against this now "foreign" antigen. These antibodies develop during neonatal life and are almost certainly a response to Gal-expressing viruses and microorganisms that colonize the primate's gastrointestinal tract.[13]Antibodies that develop in this way are known as natural or preformed antibodies (and are believed to be T-cell-independent), as opposed to elicited antibodies (T-cell-dependent) that develop after direct exposure to an antigen (e.g., antibodies that develop after an organ transplant).

Genetic engineering techniques allow for the insertion of a gene (a transgene) or for the knockout of a gene. Knockout of the gene for the enzyme *α*1,3-galactosyltransferase, which adds the Gal sugar to

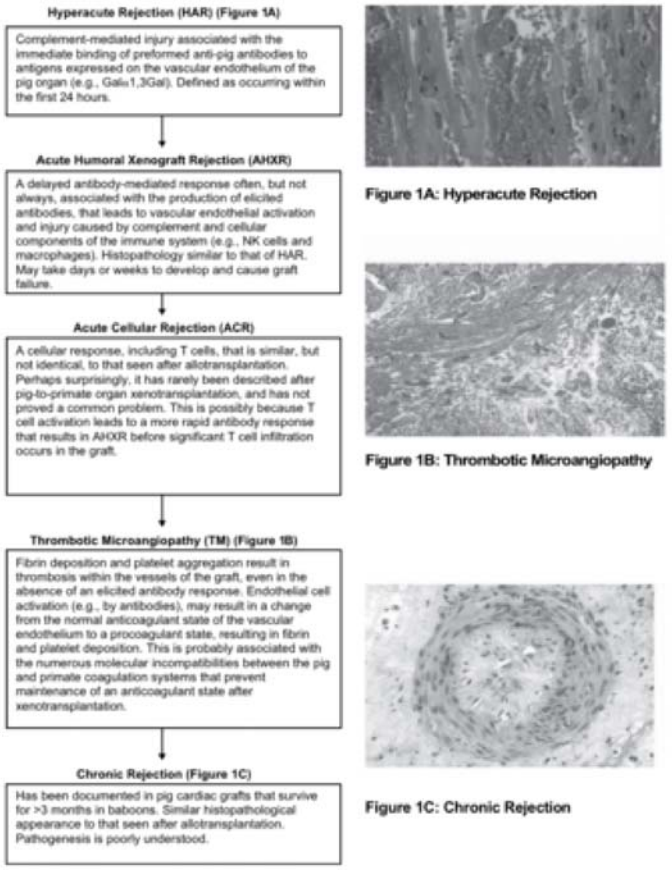

Figure 1A: Hyperacute Rejection

Figure 1B: Thrombotic Microangiopathy

Figure 1C: Chronic Rejection

oligosaccharide chains, results in so-called α1,3-galactosyltransferase gene-knockout (GTKO) pigs.[14,15,16] These pigs no longer express the Gal antigen and are relatively protected from hyperacute rejection.

Additional genetic modifications of pigs have helped further. The cells of humans are to some extent protected from complement-mediated injury by the presence of complement-regulatory proteins on their surfaces (e.g., decay accelerating factor [DAF, CD55],[17] membrane cofactor protein [MCP, CD46][18]). Although pig cells have equivalent complement-regulatory proteins, these are less able to provide protection from the effects of human complement. The expression of high levels of a human complement-regulatory protein in the pig vascular endothelium provides considerable protection from hyperacute rejection. The combination of GTKO and complement-regulatory protein is even more successful[19] and prevents hyperacute rejection from occurring.

If hyperacute rejection is prevented, a similar form of rejection can occur but generally takes a few days to develop. This is known as "acute humoral xenograft rejection" (AHXR) (Figure 69-1) and is probably also related to the deposition of antibody and complement, which activate the endothelium,[20] and the effect of graft infiltration by innate immune cells (e.g., polymorphonuclear leukocytes, macrophages, natural killer [NK] cells) that together destroy the graft. When a GTKO pig organ has been transplanted, the antibodies involved are natural antibodies directed against non-Gal antigens, the exact nature of which remains uncertain.[6,21]

Humans are known to have natural antibodies to at least one other antigen on pig cells, namely N-glycolylneuraminic acid (NeuGc).[22] However, as all nonhuman mammals express this oligosaccharide, including Old World nonhuman primates such as chimpanzees, it is impossible to investigate its effect in in vivo experimental models (e.g., pig-to-baboon organ transplantation). All information, therefore, has to be obtained from staining of pig tissues for expression of NeuGc and laboratory assays such as antibody binding assays (flow cytometry) and serum cytotoxicity assays using human sera. In some cases, these indicate that NeuGc may be at least an equal of, or an even greater barrier to, clinical xenotransplantation than Gal. There is increasing evidence, therefore, that this antibody-antigen interaction will need to be prevented if a pig organ or cells are transplanted into a human patient; the recent production of pigs in which the gene for NeuGc has been deleted (as well as that for Gal) is a major step toward this goal.[23]

In addition, if the recipient's T-cells are not suppressed by pharmacologic immunosuppressive therapy, elicited anti-nonGal antibodies develop and contribute to destruction of the graft.[6,7] The histopathologic picture of AHXR is similar to that of hyperacute rejection, but cellular infiltration is more prominent.

Pure acute cellular rejection, caused largely by infiltrating T and B cells (Figure 69-1), as seen in allografts, has to date been seen rarely in xenotransplantation. It would appear that AHXR develops before acute cellular rejection or that the immunosuppressive regimens that have been used experimentally are largely efficient in preventing T-cell activation and T- and B-cell infiltration of the graft.

Here again, genetic engineering of the organ-source pigs may prove beneficial. Pigs transgenic for the T-cell costimulation blockade agent, CTLA4-Ig, have been produced successfully.[24] In vitro assays demonstrated the immunosuppressive effect of human T-cell activation. Blood levels of soluble CTLA4-Ig in these pigs were between 10- and 100-fold higher than the therapeutic level aimed for in patients receiving the agent after organ allotransplantation. Although these data indicated the great success of the genetic engineering, the high levels of CTLA4-Ig rendered the pigs immunocompromised, prohibiting their long-term survival. Subsequent efforts have been directed toward expressing CTLA4-Ig in only selected tissues (e.g., the islets). With such local expression, the pigs are healthy; yet when the islets are isolated and transplanted into a recipient nonhuman primate, they provide a local immunosuppressive effect.

A second approach has been to express a mutant human major histocompatibility complex (MHC) class II transactivator gene in the pig. This results in downregulation of swine leukocyte class II expression and reduces upregulation of expression after activation of the pig endothelial cells, thus reducing the human T-cell response.[25] In vitro studies have confirmed the beneficial effect of this approach, and in vivo studies are presently under way.

If both hyperacute and AHXR can be prevented, then the grafts have to date failed from the development of a thrombotic microangiopathy (TM) (Figure 69-1B).[26,27,28] Small vessels in the graft become occluded by fibrin and platelet aggregation. When this becomes advanced, the loss of platelets and clotting factors in the graft may result in the development of a consumptive coagulopathy in the recipient primate.[29] The initiating cause of the TM is almost certainly immune-related and probably results from activation of the vascular endothelial cells by antibody and complement, changing the phenotype of the cells from an anticoagulant state to a procoagulant state. However, there are several known incompatibilities in the coagulation/anticoagulation factors between pig and primate that almost certainly contribute to coagulation dysregulation between graft and host.[6,7,30] Furthermore, the mechanism is complicated in that not only do the activated porcine endothelial cells express high levels of tissue factor (a procoagulant molecule) and increased tissue factor activity, but exposure of primate platelets and monocytes to the porcine endothelial cells results in increased tissue factor activity on these primate structures also.[29,31]

This problem may be surmountable by further genetic manipulation of the organ source pig (e.g., by the insertion of an "anticoagulant" or "antithrombotic" gene, such as thrombomodulin, endothelial protein C receptor, tissue factor pathway inhibitor [TFPI], or CD39).[32] By suppressing tissue factor activity on the porcine endothelial cells, TFPI may prevent the change to a procoagulant phenotype and may also prevent activation of the recipient cells and platelets. CD39 is another critical thromboregulatory molecule on endothelial cells that may limit platelet activation. The expression of several of these genes may overcome this problem, but additional drug therapy to maintain an antithrombotic state may be required. This may, however, be as simple as administration of aspirin or other oral antiplatelet agent.

Chronic rejection (graft atherosclerosis) has been documented in pig cardiac xenografts that have functioned for more than 3 months in baboons and has a similar histopathological appearance to that seen after allotransplantation (Figure 69-1C).[26] Its pathogenesis remains poorly understood but is almost certainly associated with a prolonged low-grade immune response.

Cell Xenotransplantation

Considerable attention has been paid to the transplantation of porcine islets of Langerhans as a means of providing a source of insulin in patients with type 1 diabetes.[3]

Islets from adult wild-type (unmodified) pigs, if carefully isolated, do not express the Gal epitope, and therefore the problem of anti-Gal antibodies is negated. Although adult porcine islets do not express Gal, fetal and neonatal islets (that may prove preferable sources of islets for clinical transplantation) do express Gal, and therefore GTKO pigs would be essential, or at least preferable, in these cases. Similarly, NeuGc will require deletion. Cell xenotransplants, such as those of carefully isolated islets, contain few or no vascular endothelial cells and are therefore to some extent protected from the early humoral response and are rejected largely by a cellular mechanism, as are allografts. This can be inhibited by currently available immunosuppressive agents, particularly those that result in blockade of T-cell costimulation. Currently, genetically engineered adult porcine islets have been demonstrated to maintain normoglycemia in diabetic monkeys for periods in excess of 1 year,[33] and wild-type (unmodified) adult and neonatal pig islets for periods in excess of 6 months.[34,35] However, the immunosuppressive regimens utilized in these studies would not be clinically applicable; therefore, current studies are aimed toward reducing the intensity of the immunosuppressive regimen and ensuring that all agents administered are approved for use in human patients.

The current site of transplantation of both alloislets and xenoislets is the portal vein, where the islets lodge in the liver. Direct contact between islets and blood leads to an immediate inflammatory response that destroys a large percentage of the islets infused; this is known as the instant blood-mediated inflammatory reaction (IBMIR).[36] It is a response to cells that are not normally present in the blood—in this case, the islets. Until recently, it was thought to be primarily a nonspecific inflammatory response that involved activation of the coagulation and complement systems. Recent evidence strongly suggests that the antipig immune response is playing a significantly greater role and that IBMIR may even be a form of hyperacute rejection.[37] It can be reduced, though not completely prevented, by treatment of the recipient with anticoagulant and anticomplement agents, but genetic engineering of the pig will probably prove more beneficial.

To date, genetically engineered pigs that express the complement regulatory protein CD46 have proved to be the most successful sources of porcine islets, achieving maintenance of normoglycemia in diabetic monkeys for periods extending for more than 12 months.[33] The expression of CD46 probably reduces IBMIR but also is beneficial in protecting the islets long term. More recently, the availability of pigs that express not only CD46 in the islets but also an anticoagulant/antithrombotic gene, such as TFPI and/or CD39, have also shown encouraging results, with maintenance of insulin-independent normoglycemia for more than 1 year. Techniques are available (e.g., by the use of an insulin-specific promoter) that enable the desired gene to be expressed in the islets alone, thus negating any potential detrimental effects (e.g., systemic anticoagulation) that might result from widespread expression in the pig. However, success has not yet been consistent, and further study is required.

An alternative approach that is being explored by some groups is encapsulation of the islets before transplantation into various sites in the recipient (e.g., peritoneal cavity, muscle, subcutaneous fat). The capsule is designed to prevent harmful antibodies or cells from gaining contact with the islets, thus theoretically preventing rejection or other injury and yet allowing insulin to be released from the islets and eventually enter the circulation. The great advantage of this approach would be that immunosuppressive drug therapy, with its associated long-term complications, would be unnecessary. Some encouraging results have been reported, with islet graft survival extending to 6 months in nonimmunosuppressed baboons.[38]A well-regulated clinical trial is being undertaken in New Zealand, though no results have yet been published. It appears, however, that graft survival has not been reported for longer than 6 months, and it is not known whether this is associated with eventual damage from an immune response or from loss of viability of the encapsulated islets as nutrients are no longer able to reach and sustain them.

Similar studies are progressing with encapsulation of hepatocytes, aimed as a means of treating acute hepatic failure.

Pig Neuronal Cell Xenotransplantation

Several degenerative neurological conditions (e.g., Parkinson disease) might be cured or improved by the transplantation of embryonic pig neuronal precursor cells that would produce the hormone that is deficient (e.g., dopamine). The transplantation of pig neuronal cells expressing an immunosuppressive agent, LEA29Y (belatacept), has resulted in remarkable improvement in movement of monkeys with a Parkinson-like condition, though systemic immunosuppressive therapy was also administered.[39]Some of these monkeys developed a neoplastic complication, posttransplantation lymphoproliferative disease, suggesting that the immunosuppressive therapy was excessive. However, these results were encouraging and indicate the potential of xenotransplantation in diseases that affect millions of humans.

Pig Corneal Xenotransplantation

Worldwide, particularly in Asia and the developing world, there is a critical shortage of deceased human corneas for transplantation into the millions of patients with corneal blindness.[40]Genetically engineered pigs offer a solution to this shortage. In vitro studies by Hara[19]and his colleagues indicate that corneal endothelial cells from pigs with specific genetic modifications are no more immunogenic than human corneal endotheloial cells. As corneas can be obtained from young healthy pigs rather than older deceased humans, there are other advantages, such as a greater number of viable cells in the cornea at the time of transplantation.[19]

Furthermore, because the cornea is very poorly vascularized, it has some degree of "immune privilege," making it less susceptible to rejection than other organ transplants. Corneal transplantation from wild-type (unmodified) pigs has resulted in graft survival for several weeks or months in nonhuman primates that received only local immunosuppressive therapy (i.e., injection of a corticosteroid into the cornea). The pig cornea can also be decellularized ex vivo, leaving only a "scaffold" of collagen matrix and, after transplantation into a nonhuman primate recipient, is recellularized by host T-cells. This procedure reduces the immunogenicity of the graft further.

Pig Red Blood Cell Transfusion

In many parts of the world, there is an extreme shortage of blood for transfusion, and this shortage has become exacerbated by the high incidence of human immunodeficiency virus (HIV) in several countries,

limiting the availability of acceptable blood donors. Initial in vitro studies of red blood cells from GTKO pigs indicate that, though not yet comparable to human ABO-compatible red blood cells (RBCs), they are equivalent to ABO-incompatible RBCs.[41]Further genetic manipulation (e.g., deletion of NeuGc) may enable them to become a successful alternative to human RBC transfusion.

Induction of Tolerance to Pig Organs and Cells

The ideal goal in both allotransplantation and xenotransplantation is the induction of immunological "tolerance," in which the immune system of the recipient is manipulated so that the transplanted organ or cells are accepted as "self'" with no effort made to reject them. The identification and availability of the "donor" prior to the transplant allows the procedure to be "timed" and may facilitate the induction of tolerance to the transplanted organs of cells. Efforts in this respect have been made through inducing hematopoietic cell chimerism,[42]or by pig thymic transplantation,[43]but without complete success to date.

PHYSIOLOGIC DIFFERENCES

The physiological aspects of xenotransplantation have been reviewed.[44]Evidence from pig organ transplantation in nonhuman primates indicates that the function of a life-supporting pig kidney is adequate for periods of up to 3 months before thrombotic microangiopathy (TM) and/or AHXR intervene. However, albuminuria is problematic, and it is not yet known whether this is the result of an ongoing low-grade immune response or a physiological incompatibility. Phosphate metabolism has also been reported to be abnormal. Heterotopic heart transplants have functioned for periods of up to 8 months, though life-supporting orthotopic heart transplants have been documented for less than 2 months. These studies suggest that, from a physiological perspective, these pig organs will function satisfactorily if transplanted into humans.

The liver produces approximately 2,000 different proteins and is much less likely to be physiologically compatible after xenotransplantation. Many of the porcine proteins may not function adequately in a primate host. The liver may, however, function adequately for sufficiently long to allow it to be used as a bridge to allotransplantation in patients with acute liver failure who would otherwise die within days. If one or more pig proteins (e.g., albumin) do not function satisfactorily in a human host, it will be possible to express the human gene for the specific protein in the pig by genetic engineering techniques.

As mentioned, there is clearly significant dysregulation between the coagulation systems of pig and primate, which are problematic but steadily becoming resolved. As the liver is the major source of complement in the body, after porcine liver transplantation the liver will produce pig complement, rather than primate complement, and it is known that this is less destructive to porcine cells than primate complement. This may, therefore, prove an immunologic advantage after liver xenotransplantation.

POTENTIAL INFECTION RISKS

Immunosuppressed patients undergoing allotransplantation are at risk from the healthcare-associated or opportunistic infections that may develop in any subject with a depressed immune system. Patients with xenografts will be at the same risk. However, concern has been raised about the potential for the transfer of a porcine microorganism or virus with the transplanted organ into the recipient and, perhaps more importantly, of the potential risk of the transfer of that infectious agent to those who come into contact with the recipient.[45]These would include not only relatives and friends but also members of the medical and nursing staff.

It will, however, be possible to monitor the organ-source herd at frequent intervals (before their organs are used) to ensure the absence of significant microorganisms. The housing of pigs under isolation conditions will prevent contact with other animals or insects and also minimize the risk of the transfer of an infection from a human handler to the pigs. All feed and supplies coming into the pig facility will be sterilized. The herd should, therefore, be free of all significant infectious agents.

The existence of porcine endogenous retroviruses (PERVs), which are present in the genome of every pig cell, will clearly ensure that these are transplanted with the organ. Although PERVs do not appear to provide problems in pigs—and though their equivalent, human endogenous retroviruses, do not appear problematic in humans—concern has been raised that PERVs might be problematic in a human host, particularly if that host is immunosuppressed. Although PERVs can transfer from a pig cell to a human cell under specific in vitro co-culture laboratory conditions, there has to date been no evidence of transfer of PERVs to a human or nonhuman primate in vivo.[46,47]The risk, therefore, appears to be small.

Furthermore, techniques such as RNA interference (RNAi) are currently available that could suppress activation of PERVs and prevent proliferation after transplantation.[48,49]PERVs would also appear to be susceptible to treatment by certain pharmacologic agents. This potential problem, therefore, does not appear to be one that would prevent clinical trials of xenotransplantation if the benefits of those trials are likely to be considerable to the patients.[50]

With respect to certain infectious agents, there are significant advantages of xenotransplantation. For example, in most allotransplants, one or more potentially infectious viruses, such as cytomegalovirus (CMV) and Epstein-Barr virus (EBV), are transplanted with the organ. The organ-source pig will be free of these viruses. Furthermore, certain herpes viruses (e.g., CMV), hepatitis viruses (e.g., Hepatitis B and Hepatitis C), and HIV are thought incapable of infecting porcine cells. This would prove a significant advantage if a pig liver was transplanted into a patient with, for example, Hepatitis B, as the liver may not become re-infected, which is the norm when an allotransplant is carried out.

REGULATION

Xenotransplantation will be regulated by authorities such as the U.S. Food and Drug Administration (FDA) and equivalent national organizations elsewhere. Regulatory oversight of xenotransplantation will be more rigorous than that of allotransplantation. The xenograft will be a "biological product," and the transfer of microorganisms, such as CMV or EBV, will almost certainly not be permissible. Most regulatory concerns are therefore concentrated on the potential transfer of an infectious organism to the recipient and particularly to the public at large. Guidelines have been drawn up by several national committees or regulatory authorities that indicate the circumstances under which a clinical trial of xenotransplantation would be permissible. In most cases, monitoring of the organ-source pig herd before the transplant and monitoring of the recipient after the transplant receive priority.[51]

In the initial clinical trials of xenotransplantation, both the human recipient and his or her close relatives and friends may require monitoring for signs of infection for many years. It will therefore be important that recipients and their families provide fully informed consent for this experimental form of therapy. Furthermore, once the xenotransplant has been undertaken, even if it proves unsuccessful and the graft is destroyed or removed, the patient will continue to need to be monitored, possibly for his or her lifetime. In contrast to most clinical trials, therefore, it will be difficult for the patient to withdraw completely from the trial.

Discussion of such ethical aspects of xenotransplantation continue,[52] and the regulations that will be required have not yet been finalized. However, it is not thought that they will prohibit initiation of clinical trials. Unfortunately, recent clinical trials that have been undertaken in countries where that lack a national regulatory authority has caused some concern among professionals in this field.[53] However, the most recent known trial is being closely regulated by the New Zealand Department of Health.

Summary And Conclusions

Xenotransplantation offers the potential to resolve the current shortage of organs and cells for transplantation in patients with end-stage organ failure or other serious and debilitating diseases. Although organ xenotransplantation is not yet ready to be introduced as a standard practice, clinical trials of porcine islet xenotransplantation are currently under way and clinical trials of corneal xenotransplantation are being planned. There is every reason to believe that, with the currently available genetically engineered pigs and pharmacologic agents, normoglycemia could be maintained on a long-term basis in patients with diabetes. Pig corneas could provide sight for blind patients for prolonged periods of time, if not permanently. It should always be remembered that, with the ready availability of organ- or cell-source pigs, retransplantation would always be available, which is not always the case with allotransplantation. Further advances are required in the genetic engineering of pigs before organ xenotransplantation is likely to be sufficiently successful to warrant clinical trials. However, the potential benefits of xenotransplantation would be considerable and would extend to many conditions for which transplantation is not currently undertaken. Therefore, it is worth persisting in attempts to overcome the immunologic barriers that remain.

Abstract

Microorganisms have the ability to live in two forms: planktonic (free-floating) and biofilm (attached or sessile). Most medical information from the hospital laboratory deals with planktonic organisms and relates to Koch's postulates and the corresponding germ theory: one organism, one disease. However, the preferred method of microbial life, based on survival and community diversity, is the multispecies biofilm or sessile community of organisms. In fact, studies now indicate that organism survival 3.4 billion years ago was based on biofilm architecture. Historically, diseases recognized as being associated with biofilms are consistent with chronic infections such as: (1) otitis media, (2) periodontitis, (3) native valve endocarditis, (4) cystic fibrosis, (5) indwelling medical device infections, and (6) prostatitis. Today, that list has expanded considerably, emphasizing the oral-systemic link and chronic wounds. Each of the diverse niches and tissues of the human body can suffer a biofilm infection which manifests as a chronic infection clinically. Enhanced pathogenicity related to biofilms and their recalcitrant nature is associated with their chemophysical properties, acting as hydrated polymers and demonstrating properties of both liquids and solids. Biofilms also possess well-defined molecular mechanisms to produce and maintain chronic infections. Individual species are selected for in specific host environments yet any microorganism alone and/or in synergy with other microbes (even commensals) growing as a biofilm can produce infection. Biofilm infection occurs when a microbe attaches to a host surface, up-regulates up to 800 new genes producing a distinct new biofilm phenotype of the microbe and then self-secretes a polymer matrix while also incorporating fibrin and other host proteins in its protective cover. The way biofilm feeds itself is to inflame the tissues to which it is attached and extract nutrients from the plasma that percolates through its substance.

When microorganisms are up-regulated to the biofilm phenotype, there is significant negative impact on the laboratory capacity to recover the organisms, predict antibiotic susceptibility, and even provide meaningful clinical information for management of patient infection. Further, the majority of inhabitants of

a biofilm are viable but nonculturable, necessitating nonculture DNA-based techniques such as polymerase chain reaction, sequencing, and other molecular methods.

Cohabitants of a biofilm have at least 100- to 1,000-fold increase in the ability to resist antibiotic treatment and are not cleared by normal host defenses. Biofilms exchange genetic factors more efficiently and possess multiple colony defenses. Biofilms may be monospecies or multispecies, composed of eukaryote (fungus and yeast), and/or prokaryote organisms with multiple mechanisms to encourage genetic diversity, a key survival strategy. A biofilm infection when combined into one disease entity is more costly and deadly than all cancers combined. For example ventilator acquired pneumonia (67,000), chronic obstructive pulmonary disease (50,000), wounds (50,000), and all other chronic infections kill approximately 500,000 people per year. Most biofilm disease is managed by removing or replacing body parts (legs, heart valves, lungs, etc.), which should stop once we can truly understand and manage biofilm disease.

Key Concepts

- Biofilms are attached (sessile) and may be monospecies or mixed species, prokaryote, or eukaryote.
- Biofilms contain cohabiting microorganisms living in an architecturally defined, three-dimensional environment.
- Cohabitants in biofilms are often part of the host normal flora, which, because of environmental selective pressures, overgrow or replace commensal organisms (ecological hypothesis). The majority of biofilm cohabitants are viable but nonculturable, necessitating newer nonculture lab techniques.
- Biofilms attach to surfaces, which facilitates "cross-talk" between cells of divergent phenotypes and origin.
- The complexity and robustness of a biofilm is defined by its genetic and phenotypic diversity.
- Biofilms allow synergies among all the cohabitants, making each biofilm unique.
- Clinical consequences of the biofilm are:
  - Planned staging for release (metastasis) of the attached microorganism to distal sites.
  - Fragments of the biofilm with intact biofilm defenses can spread the infection.
  - Increased resistance (1,000 times or more) to physiological antibiotic concentrations.
  - Neutralization of host defense mechanisms, including phagocytosis.
  - Enhanced exchange of genetic material, with potentially more virulent phenotypes, and multidrug resistance.
  - Increased number of organisms per unit of tissue or indwelling medical device.
  - Increased occlusion and reduced flow of catheter lumens.
  - Include physical disruption and multiple concurrent strategies to suppress the reaccumulation of the biofilm.
- Prevention is preferable.

Background

This chapter describes and summarizes the growing knowledge about medical biofilms: their structure, the consequence to medical practice and infection prevention, and emerging strategies for management of biofilm. We now understand that microorganisms have the potential to live free-floating (planktonic) or

attached (biofilm), and that the latter is the preferred method of growth because it is the introductory pathway for survival. These are not mutually exclusive; organisms can and do exist simultaneously in both phenotypes. Also the surface of attachment, biotic versus abiotic (nonliving), are much more important than originally recognized.

Basic Principles

Biofilms appeared in early fossil records dating to 3.4 billion years ago. Planktonic organisms are specialized bacteria that spend an enormous amount of cellular energy on chemotaxis and methods of pathogenicity. They are associated with disease transmission and symptoms, reflecting Koch's postulates (1864), and are exogenous, often vector-associated disease unmasked in the 19th century.

Attached organisms grow in a three-dimensional architecture that is well-defined and enables diversity and cohabitation to the survivor that benefit all members of the community. They are associated with chronic infections.

There is a growing list of diseases associated with biofilms. The original diseases studied were often tissue-associated infections and included otitis media, periodontitis, native valve endocarditis, cystic fibrosis, prostatitis, and infections related to tissue/indwelling medical device (IMD) interfaces. The list also now includes sinusitis, necrotizing fasciitis, osteomyelitis, infectious kidney stones, and biliary infections. Hence, the increased role of biofilms in disease reflects the increased use of IMDs and abiotic (nonliving) surfaces to which organisms can attach.

GERM THEORY (PLANKTONIC VS. BIOFILM)

Historically, clinical microbiology has evolved by following: (1) Louis Pasteur and the germ theory of disease, which in essence says that one organism causes one disease; and (2) Robert Koch's postulates (one organism must always be found in those with the disease, must be isolated in culture from someone with disease, the isolated organism causes disease when introduced into a healthy host, and the organism must be re-isolated from the inoculated diseased host). Based on this knowledge, it was expected that efforts to eradicate the microorganisms would result in clinical improvements to the patient. The focus was on acquisition of disease from an external (exogenous) source. Progress in disease prevention and control were historical measurements of the civilization's ability to understand transmissibility.

How things have changed! In the 1960s and 1970s, nosocomial (now referred to as healthcare-associated) infections were thought to be associated primarily with normal flora, often defined as the patient's own, endogenous free-floating or planktonic microbiota. When discussing biofilms, planktonic refers to organisms that float or drift in the environment and sessile refers to organisms that are attached or established in a particular location or on a particular site. These infections were clearly associated with microbial reservoirs within the normal hosts, and the four major microbial reservoirs include the gastrointestinal tract, gynecological/urinary tract, skin, and mouth. These infections were still associated predominantly with a planktonic paradigm and its recognized mechanisms of pathogenicity.

During the 1980s and 1990s, the use of medical devices with abiotic surfaces became more common. Here, attached microorganisms existed in an attached ecosystem made up of a number of communities, composed of eukaryotic (microorganism with distinct membrane-bound nucleus) and/or prokaryotic (microorganism without a distinct, membrane-bound nucleus or membrane-bound organelles, and with DNA not organized into chromosomes) cells living in a defined, three-dimensional biofilm community.

The biofilm community is characterized by diversity both genetic (shared supragenome or polymicrobial) and phenotypic which better ensures survival of at least a portion of the biofilm which can then reconstitute the whole. Interestingly, this concept was postulated by Eli Metchnikoff as early as the 1850s.

Microorganisms, together in a nested environment, are supportive of one another and positioned in such a way as to define nutritional benefit to each other (synergies) in order to cohabit effectively. The use of antibiotics may select against planktonic phenotype of a particular species yet at the same time not affect that same microorganism growing in biofilm phenotype, thereby allowing for more individual calls to accumulate (Figure 70-1). A major feature of antibiotic selective pressure is that the biofilm phenotype loses susceptibility and grows to a higher bioburden level than its singular planktonic members. "Persister cells" in biofilms maintain consistency of cohabitants even during antibiotic therapy, being metabolically inert.

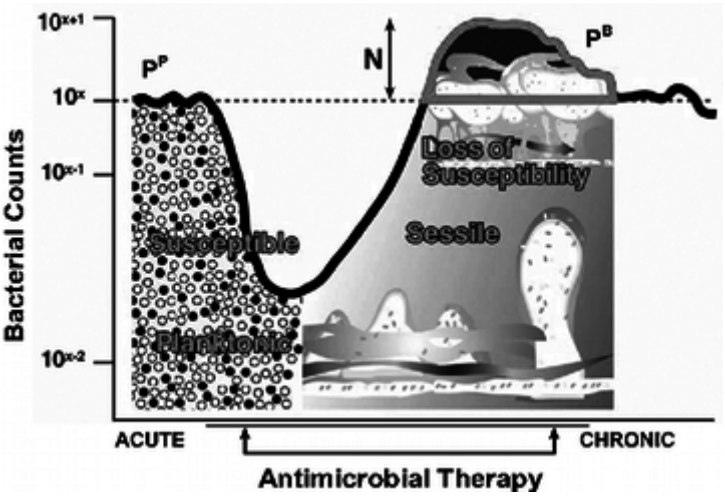

Figure 70-1.

Transition of microbial phenotypes and relationships to disease; planktonic (P^P) to biofilm (P^B).

View Image

It has been postulated that biofilms may, in fact, be a better explanation for a number of emerging diseases and for understanding the disease process of resistance. Additional diseases potentially associated with biofilms include legionnaires' disease, strep throat, *Helicobacter pylori*peptic ulcer, certain chronic bowel diseases, chronic wounds, and the oral-systemic link, in which oral plaque acts as a microbial reservoir. Also of importance to the practitioner, however, is the potential for infections associated with medical devices and IMDs. Table 70-1 lists devices used in both inpatient and outpatient populations that have potential for biofilm-associated disease.

Table 70-1 Inpatient and Outpatient Use of Indwelling Medical Devices

IMDs Associated with Inpatient Use	IMDs Associated with Outpatient Use
Sutures	Sutures
Orthopedic devices (fixators, nails, screws)	Orthopedic devices (fixators, nails, screws)

Endotracheal tubes*	Mechanical heart valve
Urinary catheters*	Voice prosthesis
Central venous catheters*	Penile implants
	Pacemakers/automated intracardiac devices
	Prosthetic joints

	Breast implants
	Dental implants
	Peritoneal dialysis catheters
*Indicates that use of the device has shifted from primarily inpatient use to increased use in an outpatient environment.	

Biofilms: Form = Function

Donlan and Costerton gave a clinical and realistic definition of medical biofilms: "The new definition of a biofilm is a microbially derived sessile community characterized by cells that are irreversibly attached to a substratum or interface or to each other, are embedded in a matrix of extracellular polymeric substances that they have produced, and exhibit an altered phenotype with respect to growth rate and gene transcription."[1]Historically, this has been a somewhat controversial definition, which has changed as more knowledge has been gained and more information analyzed. An updated version of this definition is shown in Table 70-2.

Table 70-2 Biofilms: Structure and Function where “Form = Function”

*Microbially*derived *sessile*communities characterized by:
• Cells attached to a *stratum,* or *interface*or to *each other,*
• Embedded in a *matrix*of extracellular polymeric substance *they*produced or incorporate from the environment, and
• Exhibits an altered *phenotype*with respect to *growth*rate and *gene*transcription
• Complex communities where competition is replaced by cooperation
• Advantages of cooperation include: ○ Collective action   ○ Diffusion sensing   ○ Group selection   ○ Economic use of resources
Synergies: Passive resistance Metabolic cooperation By-product influence Quorum sensing systems An enlarged gene pool with more efficient DNA sharing

The biofilm is a primitive type of developmental biology in which spatial organization of the cells within the matrix optimizes utilization of available nutritional resources.[2]Additionally, there is a mobilized enzyme system in which the milieu and the enzyme activities are constantly changing and evolving to appropriate steady states relevant to the composition and cohabitation of the members. This is a

dynamic environment in which microbial cells do reach homeostasis and in which organisms optimally organize to make use of metabolic by-products.[3] This steady state can be radically altered by applying physical factors, two of the most important being the application of high sheer and nutritional availability.

There is a great phenotypic heterogeneity within the biofilm community, with numerous microenvironments (Table 70-3). In a poetic sense, a biofilm is an ecological consortium of (usually) mixed bacterial species evolved for its survival by biodiversity. The principle is through diversity—as long as one member survives it can rebuild the biofilm. Production of a matrix or glycocalyx containing polymeric sugars, proteins, DNA, and environmental substances enhances attachment and acts as a superficial glue and potential barrier to penetration by antimicrobials. There is an incredible metabolic cooperation. The differences in pH, oxygen tension, and electronic potential in the developing biofilm microenvironment contribute to significant changes in organism form and function after attachment.

Table 70-3 Characteristics of Biofilms—Biofilm Communities

• "Cross-talk," "quorum sensing" methods of communication between multiple prokaryotic and/or eukaryotic species
• Multispecies microbial composition reflecting site-specific microbes
• Dynamic environment, influenced by peripheral stress
• Microbial cells reach homeostasis, "persister cells" are metabolically inert
• Optimally organized to make use of available nutrients
• Show great microbial heterogeneity
• Numerous microenvironments, with pH diverse microcommunities
• Wide range of enzymatic activities

*Biofilm*is an engineering term that arose from the study of matrix properties and based on defining the impact of bacterial slime on heat exchanges, river beds, ion-exchange columns, and the interface of two distinct mediums (e.g., oil/water, air/soil). Hence, the physical parameters are best defined and quantified by engineering measurements, two of which are particularly significant to dentistry and medicine. Viscoelastic (referring to materials that are viscous and elastic) and rheological (referring to materials that flow) properties define an extremely hydrated polymer, which has both elastic (solid) and viscous (liquid-like) properties.

A key component in the maturity and evolution of biofilms is capacity for cell-to-cell communication, which can be restricted to same species or global, such as autoinducer 2. Interspecies communication is necessary for cohabitation and biodiversity within the polymicrobial biofilm. Quorum sensing is a universal feature of biofilm formation, although a number of systems have been defined that show recognizable differences within Gram-negative and -positive bacteria. *Quorum sensing*is the phenomenon that allows organisms in a biofilm to sense the cell density of its environment within the biofilm via the accumulation of present signaling molecules.

Figure 70-2 summarizes the cyclic nature and consequences in stages of biofilm growth (stages I–IV). A number of key additional features should be emphasized. The biofilm thickness on the luminal surface of an IMD is not universal, nor is the staging or activity (I–IV). In fact, it appears that often there is a quiescence behavior to the biofilm. Only "hot zones" are associated with active cyclic production of the community, which in turn is potentially associated with mechanisms of pathogenicity. The biofilm is not stiff, but rather flexible. It is often described as more like a kelp bed in the ocean, moving back and

forth with the ocean current, rather than a stiff, rigid building as in a city; more recently, authors have described it as "lava-like."

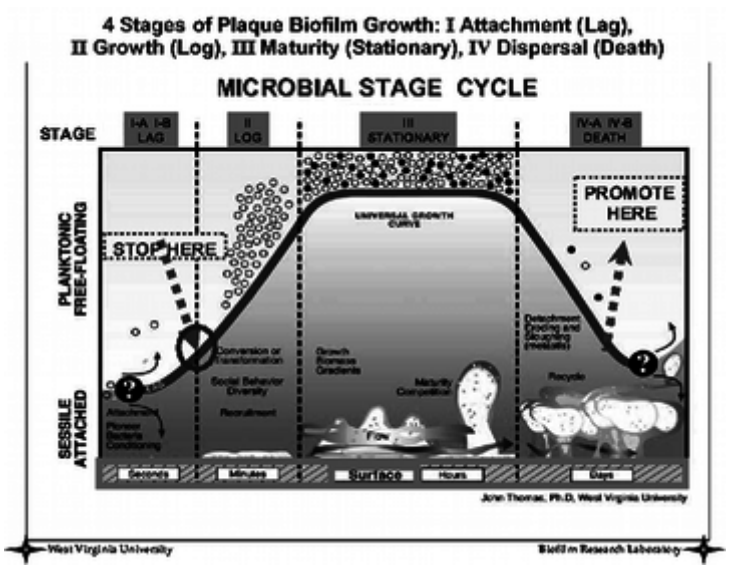

Figure 70-2.

The four stages of biofilm growt View Image

Epidemiology

There are 100 to 1,000 times more prokaryotic than eukaryotic cells living in, on, and with *Homo sapiens*, and they are predominantly anaerobic. Any microorganism colonizing the host has the potential to become a planktonic pathogen, and certain aerobic isolates have over time become marker disease organisms, associated with IMDs, as shown in Table 70-4. These are often initial or primary colonizers on the device and over time will develop a multispecies biofilm (Gram-positive and -negative organisms). IMDs of a given body site become associated with the normal flora and/or pathogens that are "native" to that anatomical location, promoting the theme that normal biofilm ecosystems are established as site specific. Biofilm development most often reflects normal flora closest to the IMD. The four reservoirs are, in order of microbial burden from highest to lowest: gastrointestinal, genitourinary (male and female), oral cavity/respiratory, and skin. Recently, the oral cavity reservoir has been expanded to include organisms causing sinusitis.

Table 70-4 Planktonic Organisms Associated with Indwelling Medical Devices

*Underline (×) denotes principal organisms.						

*Candida*species and *Candida albicans*are very frequent colonizers,[4]but are often overlooked clinically as contaminants. To put this in its proper perspective, it is necessary to understand that *Candida albicans*forms a very resistant biofilm,[5,6]utilizing its biphasic nature (yeast and hyphae), and is a reversibly adherent complex.[4]As such, it can act as an essential network for other secondary colonizers, forming a multispecies ecosystem.[7,8,9]

Although biofilms occur naturally, today's increased association between biofilms and disease reflects changes in medical practices. As noted, biofilms are the preferred method used by microorganisms for survival, especially when environmental selective pressures are present. Naturally occurring biofilms are found in drinking water lines, urban water systems, oil recovery equipment, food processing areas, ship hulls, and at any interface between a solid and nonsolid surface. The increased impact of biofilms in medicine is a result of the explosive growth in the past decade or so in the use of IMDs, including both simple and complex devices (Table 70-5).[10]Simple devices include catheters and stents. In the United States, approximately millions of catheters of all types are used annually. Coronary stents (percutaneous coronary intervention procedures) increased threefold in the 1990s. Literally hundreds of thousands of dental implant procedures (also simple IMDs) occur each year in the United States. In the complex arena, the use of automatic, implantable cardioverter defibrillators (ICD) has increased more than 100-fold since first approved in the early 1990s. Further, hundreds of thousands of knee replacements are performed in the United States annually, a number that will continue to grow. The growth in medical circulatory support is estimated to have been between 20 and 30 percent per annum between 1999 and 2004.

Table 70-5 Anti-infectives Commonly Used on Indwelling Medical Devices

Anti-infective Coating/Material	Indwelling Medical Device
Metals	
Silver	Endotracheal tubes, urinary catheters, intravascular catheters
Antibiotics	
Minocycline-rifampin	Impregnated catheters
Vancomycin (with or without heparin)	Catheter locks
Dicloxacillin	Intravascular catheter
Clindamycin	Intravascular catheter
Cefazolin with benzalkonium chloride	Catheter
Triclosan	Sutures
Anti-infective Biomaterials/Polymers	
Polypeptides	
Chlorhexidine	Sponge dressings
Chlorhexidine-silver-sulfadiazine	Impregnated catheters
Iodinated alcohol	Catheter hubs
Fusidic acid	Intravascular catheter
Hydrophilic-coated polyurethane with glycopeptides teicoplanin	Central venous catheter
Irgasan (disinfectant)	Catheter
Hydrophilic hydromer-coating	Central nervous system shunts
Other	
Polypeptides	Various experimental biomaterials

As early as 2001, preventing and controlling disease related to biofilms figured in two of the seven healthcare challenges identified by the U.S. Centers for Disease Control and Prevention (CDC): reducing hospital-associated catheter-associated adverse events by 50 percent and reducing hospitalizations and mortality from respiratory tract infections among long-term care patients by 50 percent. Biofilms are common to each of these infection types, which is not surprising since the National Institutes of Health (NIH) estimated that 80 percent of healthcare-associated infections (HAIs) are biofilm associated.[11]

More recently, campaigns including the Institute for Healthcare Improvement (IHI) 100,000 Lives and Protecting 5 Million Lives have focused on measures related to central line-, surgical-, and ventilator-associated infections. The 2008 Centers for Medicare & Medicaid Services (CMS) pay-for-performance reimbursement measures included "no pay" for HAIs, catheter-associated urinary tract infections, and central line (vascular catheter)-associated infections.

The growing impact of intravascular catheter-related infections in healthcare has been quantified. The Healthcare Infection Control Practices Advisory Committee's 2002 *Guidelines for the Prevention of*

*Intravascular Catheter-Related Infections*cites references that estimate 250,000 cases of intravascular catheter-related infections annually, with an approximate mortality of around 12 to 25 percent for each infection, with a cost of around $25,000.

Ventilator-associated pneumonia (VAP) and endotracheal tube lumen biofilms occur at a rate of 7.5/1,000 vent days in medical intensive care units (ICUs) and 13.6/1,000 vent days in surgical ICUs. VAP is associated with attributable costs in excess of $11,000 per episode and case fatality rates are about 20 percent. There are also associated increases in multidrug-resistant isolates, particularly Gram-negative isolates, after 7 days of ventilation.

Lastly, it is very important to note the two genetic studies of the NIH. "Roadmaps" are designed to unmask the resident flora of humans and the complete genotyping of these isolates, complementing the human genetic and metabolic landscape. The two studies are entitled *The Human Microbiome Project*and the *Human Oral Microbiome Database*, and complement the human metagenomics strategies employed to unmask the genetic makeup of *Homo sapiens*. Together they hope to connect normal genealogy and predisposition to disease.

Biofilm-Associated Infections

A biofilm infection begins when a single planktonic bacteria attaches to a host environment. If host defenses do not clear the bacterium within a short period of time, the microbe quickly changes to a biofilm phenotype. Attachment is a strong signal to start up-regulating operons which control as many as 800 genes whose products are specific for biofilm phenotype. The microbe undergoes a tremendous metamorphosis, much like a caterpillar to a butterfly. The bacteria, although genetically identical, phenotypically are quite different. The new biofilm phenotype microbe produces senescence of the surrounding host cells, secretes a protective matrix, and begins quorum sensing to dictate the different phenotypes throughout the biofilm community.

Once biofilm has reached a stable community (climax community), it has a problem with nutrient source. If the bacterium were to secrete virulence factors and kill its host's tissue, it would lose its stable substrate to which it is attached. Biofilm takes a different strategy in that it inflames the host tissue to which it is attached so that plasma will escape from the surrounding capillaries and percolate through the biofilm. This provides a constant and regulated source of nutrition to the biofilm community.

For biofilm to be successful in producing a host chronic infection it must be able to induce senescence in host cells. One mechanism that microbes use to produce senescence is to eject effector proteins through a type 3 secretory system. These effector proteins work directly on specific host pathways to block apoptosis, migration, and to usurp the cytoskeleton of the cell. This prevents host cells from shedding and the biofilm from losing its attachment to the host.[12]

The most common nutrient depletion with biofilms is development of an anoxic region within the core of the biofilm. In vitro biofilm models have been developed to exploit this property of biofilm to allow propagation of anaerobic bacteria in what is viewed as an oxygen environment like the surface of a chronic wound.[13]Also in vivo polymicrobial biofilm models now allow evaluation of hypoxia, pH, and species interactions. The ability of biofilms to provide an environment for anaerobic growth through oxygen depletion may be an important factor for the increase in the virulence of biofilm infections.[14,15]

Waste products, molecules that bacteria produce which are end products and are of no benefit to the metabolizing member, are released into the local biofilm environment. Many of these metabolites such as ammonia, lactic acid, and carbon dioxide can have significant influence on the surrounding microorganisms.[16] Studies have demonstrated that *Fusobacterium nucleatum* and *Prevotella intermedia* generate ammonia which raises the pH suitable for *Porphyromonas gingivalis* and that *Fusobacterium nucleatum* also provides an increased carbon dioxide environment which increases the pathogenicity of *Porphyromonas gingivalis*.[17] Also it has been shown that waste products from *Pseudomonas aeruginosa* may protect *Staphylococcus aureus* from aminoglycosides.[18,19]

Passive resistance is when one of the members in the biofilm possesses a resistance factor that can protect other members of the biofilm that do not have the factor. There are numerous biofilm defenses that limit the effectiveness of antibiotics. However, the easy sharing of mobile genetic elements, such as *mec*A cassettes and genes encoding extended-spectrum beta-lactamases, raises concern for increasing passive resistance in polymicrobial infections. For example, a beta-lactamase-producing strain of *Haemophilus influenzae* was cocultured with *Streptococcus pneumoniae* deficient in any resistance factors. *H. influenzae* increased the minimum inhibitory concentration (MIC)/minimal bactericidal concentration (MBC) of *S. pneumoniae* by amoxicillin.[20]

The clinical concern relative to the synergies of polymicrobial biofilm is that the infection will be more severe and recalcitrant to treatment. There are many examples that show that this is indeed the case. Low levels of *Pseudomonas aeruginosa* mixed with *S. aureus* increased infection rates in a rat model. In the mouse model *Prevotella* increases the pathogenicity of *S. aureus*.[21] *Escherichia coli* produced marked increase in the size of abscess formation with *Bacteroides fragilis* in a diabetic mouse model.[22] There is also clinical evidence to suggest that polymicrobial infections are more severe.[23]

As described, diseases that were historically associated with biofilms included periodontal diseases, otitis media, native valve endocarditis, cystic fibrosis, IMD infections, and prostatitis. Following is a brief description of these diseases and their associations with sessile, cohabitating communities most associated with infection prevention. This is an overview with primary emphasis on those diseases important to infection preventionists.[24,25]

TRADITIONAL: BIOTIC SURFACES

Periodontal Diseases/Subgingival Plaque

Three of the oral flora particularly associated with biofilms and the destructive process associated with periodontal disease are: *Porphyromonas gingivalis, Bacteroides forsythus*, and *Treponema denticola*.

Biofilm formation is greatly influenced by the sheer forces of supragingival versus subgingival processes. Organism population, its density, and its individual composition are influenced by the features described earlier, but particularly by sheer forces. Interestingly, there are three biofilms within the subgingival plaque: (1) the biofilm associated with abiotic surface or enamel; (2) the biofilm associated with the living tissue on the outer aspect of the periodontal pocket; and (3) the biofilm of a "flox" that is mixed species and free-floating.

The consequences of oral biofilm diseases are associated not only with tooth loss. Among women, poor oral hygiene is now known to be associated with low birth weight babies and premature ruptured

membranes. Recently, its importance in VAP, arteriosclerosis, diabetes, and others have gained national and international attention.[26]

Otitis Media

Otitis media has dumbfounded physicians and practitioners for some time, given the multitude of studies with significantly different results. We now better understand the diseases associated with biofilms and the fact that organisms grown in the laboratory in a planktonic state/environment may not predict the actual success or failure of organisms attached in the biofilm-associated disease.

Sinusitis

Rhinosinusitis infections have always been considered recalcitrant to clinical management, including "washout" techniques, which have implied biofilm resilience. Now sinus infections in general, and rhinosinusitis in particular, have been added to the list of biofilm diseases with traditional three-dimensional architecture definition (SEM 70-1). Further, the four reservoirs of *Homo sapiens*have been modified to link the sinus and mouth area as one of the reservoirs.

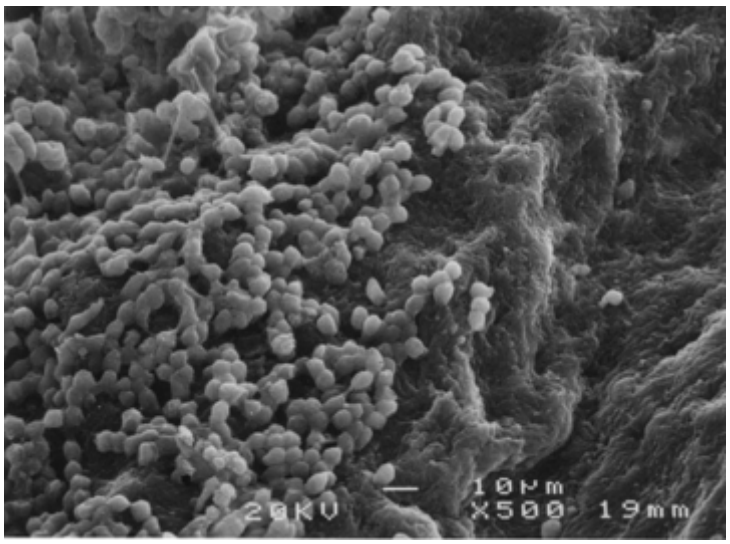

Figure 70-3.

Biofilms in chronic rhinosinusitis. View Image

Native Valve/Vascular Implant Endocarditis

Streptococci are the etiological agents in more than half of infective endocarditis cases, with staphylococci accounting for another one-fourth of cases. Many strains are common commensals of the skin and oral cavity. Endocarditis is associated with congenital heart defects, prosthetic heart valves, and vascular grafts, and is most likely caused by clots of platelet and fibrin that amass where turbulent flow is aggravated by abnormal tissue, preexisting heart disease, or an indwelling vascular catheter. Damaged endothelium exposes the underlying basement membrane, which consists of collagens, laminin, vitronectin, and fibronectin, thereby providing a substratum for bacterial adherence. Bacterial endocarditis might also illustrate how turbulent flow contributes to the formation of vegetations. Although turbulence has been traditionally thought to induce clot formation and tissue damage, it is conceivable that clumps of biofilm-associated cells respond to the turbulent flow of the cardiac environment by producing more adhesion factors called extracellular polymeric substances (EPS). Large vegetations are particularly friable and amplify the risk of embolization (detachment through clumping dispersal), which might cause infarcts and septic abscesses in other tissues.

Importantly, aggressive antibiotic therapy in the treatment of endocarditis is consistent with the role of biofilms in these infections. In vivo studies in a rabbit model with *E. coli*as the infectious agent required sustained antibiotic treatment concentrations that were 220 times the serum MBCs.

Cystic Fibrosis/Cystic Fibrosis Pneumonia

Cystic fibrosis (CF) is an autosomal recessive disease that is caused by mutations in the cystic fibrosis transmembrane conductance regulator (*CFTR*) gene, which results in dysfunctional electrolyte secretion

and absorption and results in thick, sticky mucous in respiratory and gastrointestinal tracts. Although multiple, complex physiological dysfunctions are present, the primary site of morbidity is the respiratory system. Pulmonary colonization of the lower respiratory tract of CF patients begins in infancy or early childhood, most commonly by *S. aureus*and *H. influenzae*. However, by adolescence and early adulthood, most CF patients have become colonized with *P. aeruginosa*.

There are two salient features regarding colonization of the CF lung with *P. aeruginosa*. First, *P. aeruginosa*grows in biofilms within the CF lung. Microscopic analysis of sputum from CF patients showed that *P. aeruginosa*forms biofilm-like structures consisting of clusters of bacteria surrounded by a dense matrix. The second salient feature of *P. aeruginosa*colonization of the CF lung is the selection of mucoid variants of *P. aeruginosa*, which are characterized by overproduction of the exopolysaccharide alginate and a resistance to antibiotic therapy.

*P. aeruginosa*has several adhesins and binds to a broad range of receptors and cell types in the respiratory tract. Yoon et al. have also shown that anaerobic growth might be an important feature of *P. aeruginosa*growing in biofilms in CF patients. *P. aeruginosa*formed vigorous biofilms under anaerobic conditions, leading to the buildup of toxic nitrogen metabolites. Interestingly, *P. aeruginosa*antibiotic resistance and biofilm formation seem to be induced at the same time. It was speculated that antibiotic-resistant phenotypic variants of *P. aeruginosa*observed in CF infections were either selected within biofilms by sublethal antibiotic treatment or by the specific environment of the CF lung (characterized by osmotic and oxidative stress).[27]

TRADITIONAL: ABIOTIC SURFACES

Indwelling Medical Devices

There are significant numbers and types of IMDs. Device composition is very important to the formation of biofilms. One feature in defining a biofilm's integrity, cohesiveness, and three-dimensional architecture is the substratum to which the biofilm was formed and which, for an IMD, is the material that makes up the device. Obviously, in recent years, there have been a wide variety of device materials developed. Some device materials are hydrophobic (water hating) and others are hydrophilic (water loving). Material-related factors can have an impact on the ability of an organism population to adhere.

There is one universal feature among IMDs: the potential for microorganisms to access them (they are "indwelling" in the body by definition). In the common example of a catheter introduced into the body, bacteria can access the catheter either extraluminally (outside the catheter) or intraluminally (inside the lumen of the catheter). Initially, it was felt that colonization occurred on the extraluminal or outside surface of the catheter, but recent data clearly suggest that intraluminal growth is a significant way in which biofilms maintain and survive—and potentially promote infection. The turbulent shear dynamics of fluid movement within the lumen enhances the progression and architecture of the intraluminal biofilm.

Both urinary catheters and central venous catheters have the potential for biofilm-related infectious complications via both extraluminal and intraluminal colonization. Urinary tract infections (UTIs) related to catheter use are common and, although they do not contribute as significantly to cost or mortality as central line-associated infections do, are a considerable problem in healthcare. Infections associated with central venous catheters are the most commonly described of the healthcare-associated bloodstream infections. These infections prolong the average length of stay significantly in the ICU with a concomitant significant excess cost per each afflicted ICU patient. The attributable mortality is also significant, with risk of death dependent in part on infecting organism. Staphylococci are often the infecting organism associated with a central venous catheter biofilm. However, the list of possible

pathogens also includes *Candida*species, enterococci, enteric Gram-negative bacteria, and/or environmental Gram-negatives.[28,29]

UNMASKING NEW BIOFILM-ASSOCIATED INFECTIONS

Oral

The oral cavity is now recognized as the most diverse ecosystem in *Homo sapiens*, with over 1,000 phylotypes or generally distinct microorganisms. Biofilm-associated diseases have migrated from traditional (e.g., periodontitis and gingivitis) to infections associated with dentures,[17]to systemic diseases linked to oral microbial imbalance (focusing most recently on dental plaque/biofilms) (Figure 70-3).[30,31,32]The three-dimensional structures of endotracheal biofilms also confirm the uniqueness of an oral flora signature, by emphasizing diversity (SEM 70-2). Research (NASCENT trial)[33]related to the antimicrobial activity of silver when incorporated as a component of endotracheal tubes has been promising and has resulted in the recent U.S. Food and Drug Administration (FDA) approval of a silver-coated endotracheal tube for use in patients ventilated for longer than 24 hours.

View Image

Oral Systemic Link: Oral Care

There is an accumulating body of data that implicates dental plaque as a reservoir for pulmonary infection in critical care and institutionalized elderly patients, and that instituting a program of dental hygiene can reduce episodes of healthcare-associated pneumonia (HAP).

There is historical evidence that in healthcare settings, oral hygiene undertaken on patients has been poorly performed, with inconsistent adherence to evidence-based practice. This had been especially true in the ICU, where oral care interventions focused on comfort measures rather than as a means of removing plaque and pathogens. The British Dental Society for Disability and Oral Health guidelines (2000) recommend tooth brushing to maintain oral hygiene in intubated critically ill adults. Tooth brushing is considered the most effective

mechanical tool for removing plaque. The inability of foam swabs to adequately remove plaque compared with a toothbrush is well documented in normal individuals. However, in the United States, the majority of critical care nurses prefer foam swabs, as they fear dislodging the endotracheal tube. A more recent survey of oral hygiene practices among European nurses found that the majority used oral antiseptics in preference to mechanical methods of cleaning. Strategies to reduce the risk of biofilm-associated VAP infections were published in the 2008 Society for Healthcare Epidemiology of America/Infectious Diseases Society of America hospital-associated infection compendium.[34] This guide includes recommendations to perform regular oral care with an antiseptic solution and specific strategies to minimize contamination of respiratory therapy equipment.

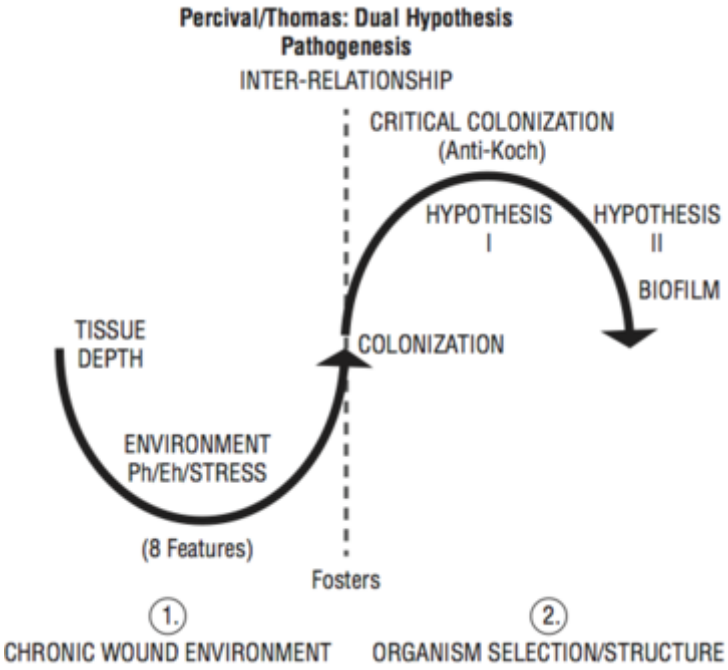

Figure 70-6.

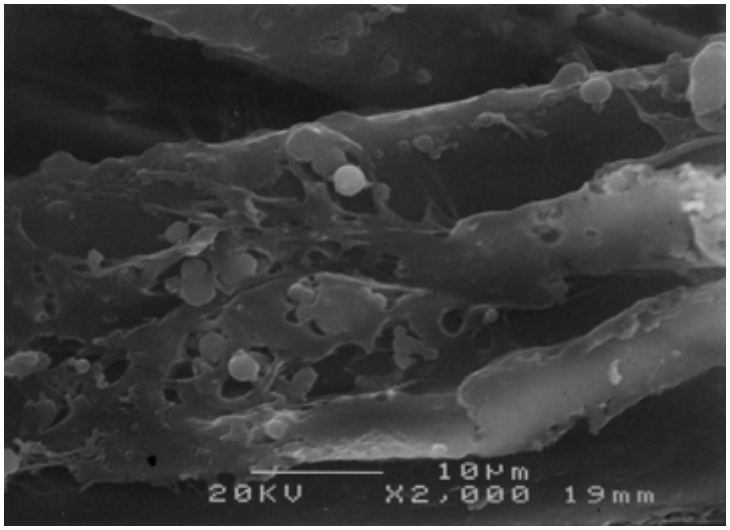
Transition of planktonic to biofil

View Image

CHRONIC WOUNDS

Chronic wounds encompass several divergent diseases all quite possibly linked to biofilms and the transition from predominantly planktonic microbial ecosystems to a complex biofilm dominated ecosystem (Figure 70-4). The factors during the transition are still to be defined, but it is increasingly clear that biofilms reduce microorganism recovery and stop planktonic cell proliferation (see Figure 70-1).



An essential transition component is critical colonization. This involves presence of bacteria on the surface of the wound and not yet into the deeper tissues, but to such an extent that the buildup of secreted toxins, as well as host cell cytokines and proteases, impairs the healing progress. Because critical colonization does not involve the invasion of bacteria into viable tissues, local clinical signs of redness, pain, heat, and swelling are usually not manifest. However, other more subtle clinical signs may indicate that superficial bacterial levels are delaying healing. The critically colonized wound can appear healthy, with an absence of nonviable tissue. However, the granulation tissue may have a characteristic color and texture, in which healthy granulation tissue is often described as beefy red; the granulation tissue in a critically colonized wound may appear bright red in color, foamy in appearance, and may bleed quite easily. Critically colonized wounds also may exhibit new areas of tissue breakdown, bridging of epithelium, and sudden odor and increased exudate production. Yet, in many cases, the only sign of critical colonization of the wound surface may be a plateau in healing progress.[35,36]

Figure 70-7.

Biofilms in braided sutures.

View Image

The progression to wound healing may become compromised by the biofilm community—that is, the microbial-to-host balance is weighted in favor of the microorganisms—and the term *critically colonized* has been used to describe this state. At this stage, the microorganisms, while interfering with the wound healing process, may not necessarily induce any clinical signs of infection, although there

may be subtle signs that indicate bacterial imbalance (e.g., change in wound color or odor together with the presence of revitalized tissue and ischemia).[37]

A consequence of new biofilm information is that both sutures and dressings are now recognized as potential devices that can provide an abiotic surface for growth. Scanning electron micrograph images show a braided suture filling the spaces between the braids (SEM 70-3); several investigators recognize that gauze may act as a "biofilm reactor," providing a rebound surface for biofilm structures in a protected environment. Hence, it is not surprising that a number of gauze incorporate silver, CHG, PHMB, iodine, and other anti-infectives, whose benefit still needs clarification.

Laboratory Diagnosis

Diseases associated with biofilms offer very unique and perplexing problems for the diagnostic laboratory. Since the evolution of the germ theory and the preponderance of one organism, one disease concepts, microbiology laboratories have used both broth and solid mediums that focus on isolation of planktonic microorganisms.[38,39,40]Hospital laboratory testing does not specifically detect biofilms. For central line catheters, catheter tip cultures can be misleading. The traditional method of the Maki roll technique requires concomitant blood samples within 24 hours.[40]

Advances in non-culture-based laboratory techniques have been used to circumvent the issue of multispecies biofilms containing nonviable and/or viable but nonculturable cells. A variety of molecular methods, including polymerase chain reaction (PCR) coupled with density gradient gel electrophoresis (DGGE), have been applied to laboratory work on biofilms.[41]In addition, quantitative scanning microscopy techniques have been employed to unmask the magnificent heterogeneity and complex biofilm ecosystem, particularly in wounds. These techniques are not used in the routine hospital laboratory, but are instrumental in biofilm research and investigational laboratories.

DIAGNOSING POLYMICROBIAL COMMUNITIES

The clinical significance of shared genetic information, metabolic synergies, and coaggregation/colocalization symbiosis is that new diagnostic and therapeutic methods will be required. Since, as discussed above, minor bacterial constituents can provide a multitude of different advantages to their neighbors, including increased virulence, then it becomes important to identify all the species present and their relative contribution to the infection. Clinical diagnostic methodologies are focused on identifying the most abundant organisms producing an infection, but for biofilms this will have to give way to methods that can identify and quantitate each individual member of the polymicrobial community. Molecular methods have demonstrated the ability to precisely define the identity and quantity of each species of a polymicrobial biofilm infection.[42,43]

The 16S ribosomal DNA (rDNA) has been called the genomic fingerprint, and molecular methods (PCR and sequencing) evaluating the 16S rDNA region are usually capable of reading this genomic fingerprint.[44] PCR methods are more suited to looking at unique genetic targets within a particular species but are also used to evaluate the 16S rDNA. However, the specificity of PCR is a limitation in that microorganisms can only be identified if a specific primer is developed and validated. Because there are thousands of different species present in biofilm infections this is currently impractical. To avoid the necessity of developing an almost infinite number of primers, innovators have integrated PCR of the bacterial 16S ribosomal DNA gene with rapid evaluation of this gene utilizing mass spectroscopy. The Plex ID (Abbott Molecular, Des Plaines, IL) utilizes multiple general primer sets to cover the different variable regions of the 16S rDNA as well as other chromosomal and plasmid regions so that the vast majority of the currently reported bacterial species can be identified. By utilizing advanced mathematical algorithms, segments of the 16S rDNA can be correlated with specific species with a very high level of confidence. This allows rapid same-day identification and some quantitation of the more prevalent organisms within a polymicrobial infection.

Sequencing technology such as pyrosequencing based on a light signal accurately determine the sequence of long segments of specific regions of bacterial DNA, such as the 16S ribosomal gene. These technologies can give a 99 percent accurate code for the 16S gene that is then compared against accessible databases to identify the microorganism with a high degree of certainty. The copy number for each specific organism can be compared to the total number of copies for all organisms providing good relative quantification for each microbial species present.

An issue is whether the bacterial DNA identified is from bacteria that are alive. Post et al. reported "These findings indicate that purified DNA and DNA from intact but nonviable bacteria do not persist in the middle ear cleft in the presence of an effusion."[45] So it seems likely that the majority of organisms identified by their DNA are indeed viable organisms.

Molecular methods, even at this early stage, can handle the challenges of correctly diagnosing polymicrobial infection. Once good DNA is obtained, most molecular platforms are extremely capable of accomplishing their analysis. Yet cleaning up the data post analysis such as chimera checking, noise suppression, and data housekeeping after the run is critical. Reporting the identification and amounts of the organisms present requires complex bioinformatics to reduce the massive data down to reliable, clinically useful results. Yet, with all these technical hurdles, molecular methods have demonstrated the unique ability to reliably evaluate biofilm infection.[46]

Another avenue of biofilm research is in the arena of susceptibility testing of antimicrobials. The use of a poloxamer in this type of investigation has gained international recognition. A poloxamer is a reverse gel. It is liquid at 4°C and is a solid at 37°C. Because of its chemical composition, the poloxamer induces the biofilm's phenotype and allows for standard disk susceptibility methods (although the drug concentrations need to reflect the recalcitrant nature of biofilms and the site of the IMD).

Treatment And Prevention

Treatment and management of biofilm-associated diseases is complicated by the same difficulties described for laboratory detection; namely, that biofilm diseases are difficult to treat, often hard to detect in their chronic association, and not manageable with the traditional antimicrobial schemes based on planktonic free-floating germ theory life forms. Given that organisms have the potential to be biphasic

(or two life forms, planktonic or sessile), antimicrobial therapies must address both the sessile and planktonic forms of an individual or mixed species consortia (see Table 70-6).

Table 70-6 Medical Biofilm Diseases

Probable	Possible	Generally Accepted		
Nasal polyps	Epididymitis	Atherosclerosis	Otis externus	Periodontal disease
Conjunctivitis	Urinary stones	Diabetes (pancreatic beta amyloid formation)	Otitis medius	Osteonecrosis of the jaw (bisphosphonate therapy)
Iritis	Chronic pancreatitis	Alzheimer disease (beta amyloid formation)	Cholesteatoma	Mastitis
Chronic bronchitis	Ascending cholangitis	Multiple sclerosis	Mastoiditis	Ventilator acquired pneumonia
Asthma	Atopic dermatitis	Chronic inflammation induced cancers	Chronic tonsillitis	Cystic fibrosis
Duodenal ulcer	Psoriasis	Autoimmune diseases	Chronic rhinosinusitis	Gastric ulcers (*Helicobacter pylori*)
Crohn disease	Burns	Altered commensals (autism, mood, obesity)	Osteomyelitis	Chronic obstructive pulmonary disease
Ulcerative colitis	Surgical site infections		Chronic meningitis	Peritoneal dialysis catheters
Diverticulitis	Folliculitis		Ventricular shunt infections	Urinary catheters
Proctitis	Abscess		Amniotic fluid sludge	Intravenous catheters
Pelvic inflammatory disease	Chronic vaginosis		Bacterial endocarditis	Infected medical devices
Chronic prostatitis	Postoperative endophthalmitis		Wounds	Gallstones
Interstitial cystitis				

Several features are often considered when designing and implementing new antimicrobial strategies directed toward biofilm diseases. It is important that an antimicrobial's molecular weight, size, configuration, pH activity, and antiquorum sensing are appropriate for the biofilm environment. Clearly, the antimicrobial's half-life, serum binding, and concentration-dependent (CD) or time-dependent (CI) properties are applicable to the nonbiofilm form, but may have little or altered impact on biofilm-associated central line-associated infections and VAP. These are areas in which significant improvement in antimicrobial treatment and management should be made.

Catheter removal could be the most effective treatment and is often the treatment of choice. For urinary catheters, this can be the best option. However, this may be impractical or impossible for central venous catheters, especially if it means loss of the only available access site, or if it may lead to a difficult procedure based on the patient's clinical situation.

*Prevention is better than cure.*New prevention strategies are being developed. One of these incorporates a beneficial biofilm mediated by use of probiotics (providing supplements of "good" bacteria). Names imply approach: replacement therapy, biotherapy, competitive exclusion bacteriotherapy, and therapeutic microbiology. The probiotic organisms need to have a stable, selected competitive advantage and be able to establish biofilm "residency." A preparation containing *Lactobacillus*species has been used in Japan since 1995 and in the United Kingdom since 2008 (introduced in the United States in January 2009), and has been effective in reversing periodontal and gingival diseases. Over-the-counter probiotics, which most typically contain *Lactobacillus*, *Bifidobacterium*, or yeast such as *Saccharomyces*, have been used with varying degrees of effectiveness in clinical and nonclinical settings.

An effective and sometimes underutilized approach in the management and treatment of biofilm-associated infections related to central venous catheters is the catheter care team. The team is developed around standardized, best practice patient care, including sterile insertion practice and appropriate dressing and wound care. The team can be expected to have a high level of expertise and provide good case monitoring. When a catheter care team is in place they will play an essential role in good infection prevention related to central line-associated infections. These teams bring standardization and best practices to site preparation and procedural techniques, and can determine appropriateness of antimicrobial bonded catheters and prophylactic locks. The best practice "bundled" approach for prevention of catheter-associated infections (often used by catheter teams) has received much interest in recent years and is reviewed in the HAI compendium on central line-associated bloodstream infections (also see Supplemental Resources and **34. Intravascular Device Infection**).

Conclusions

The biofilm phenotype is the preferred method of microorganism growth; given the option of existing as free-floating, planktonic form or within a biofilm, organisms preferentially attach and adhere. Clinically, biofilm phenotypes are associated with survival and planktonic with symptoms. Attachment can occur on abiotic (IMDs) or biotic (sloughing) surfaces and require unique adaptations and cross-talk among cells and across species (as well as across prokaryote or eukaryote types). Recently, biofilms have been recognized as being associated with chronic infections, particularly chronic wounds. In the oral cavity, plaque biofilms have been identified as a reservoir for oral-systemic infections, particularly VAP. Therefore, interventions to reduce the risk of VAP require reassessment of and compliance with good oral care in the ICU setting.

Biofilms confer unique characteristics to normal flora isolates that are up-regulated to a biofilm phenotype. These include development of higher organism concentrations, loss of antibiotic susceptibility, enhanced virulence, and altered cellular expression. Biofilms offer very unique and partially unrecognized challenges to detection and recovery by the microbiology laboratory. The biofilm characteristics are best defined by engineering criteria, especially viscoelastic and rheology. Normal, traditional strategies for biofilm elimination and control do not work well in medical practice, where the number of biofilm-associated diseases is increasing.

Future Trends

It is becoming quite apparent that biofilms are an integrated part of *Homo sapiens*, and may be one of the best defenses against introduction of foreign or unbalanced microbial ecosystems. Hence, a new

strategy might employ a two-pronged approach: (1) abiotic surfaces (IMDs) coated with anti-infectives against selected "marker" organisms, essential for biofilm three-dimensional integrity and structures ("smart devices"); and (2) biotic surfaces colonized with replacement therapy organisms, or probiotics, that reinforce the beneficial normal flora of the sites at risk ("smart probiotics") or site specific.

Both of these options are incumbent upon markedly improved laboratory detection utilizing culture independent methods (molecular) and new susceptibility testing of mixed species in a biofilm phenotype (poloxamer). The new important species will be recognized by the ongoing studies at the NIH, dealing with the Human Microbiome Project and the Human Oral Microbiome International Database.

APIC TEXT OF INFECTION CONTROL AND EPIDEMIOLOGY

Bordetella pertussis

Author(s): Amanda M. Valyko, MPH, CIC
Infection Control Practitioner

University of Michigan Health System
Ann Arbor, MI

Published: October 3, 2014

Abstract

Bordetella pertussis*is a highly communicable, acute, infectious respiratory disease that remains a cause of high morbidity and mortality among children worldwide. Reinfection is common in both previously vaccinated and nonvaccinated individuals. Asymptomatic and subclinical infections occur frequently among adolescents and adults. Macrolide agents are the drugs of choice for treatment and prophylaxis of pertussis. Acellular vaccine is available for infants, adolescents, and adults, including pregnant and postpartum women in the United States. Specific interventions are required to prevent the transmission of disease.*

Key Concepts

- Pertussis epidemics occur in cycles of 2 to 5 years.
- Vaccination immunity for pertussis wanes over time.
- Pertussis is highly contagious and has an impact on both the community and healthcare facilities.
- The diagnosis of pertussis can be made through direct culture, direct fluorescent antibody testing, or polymerase chain reaction assay.
- Clinical manifestations of pertussis are broken down into two stages: the catarrhal stage and the paroxysmal stage.
- Vaccines are available.
- Both community outbreaks and healthcare setting outbreaks have been reported.

Background

Pertussis (whooping cough) is a highly communicable, acute, infectious respiratory disease caused by *Bordetella pertussis*. *B. pertussis*is a small, aerobic, Gram-negative pleomorphic bacillus (0.2 to 0.5 µm in diameter). The bacteria are fastidious and difficult to culture and have an incubation period of 10 to 14 days. *B. pertussis*produces multiple antigenic and biologically active products, including pertussis toxin (PT), filamentous hemagglutinin (FHA), agglutinogens, adenylate cyclase (AC) toxin, pertactin, fimbriae, tracheal colonization factor, and tracheal cytotoxin (TCT), which are responsible for the clinical features of pertussis disease.[1,2]Two closely related organisms are *Bordetella parapertussis*, which causes a pertussis-like syndrome in humans, and *Bordetella bronchiseptica*, which produces respiratory tract illness in animals, although it has been occasionally reported in humans, including several case reports of *B. bronchiseptica*infection in HIV-infected patients as well as a single case report of an immunocompetent infant with recurrent pneumonia due to *B. bronchiseptica*.[3,4]

Basic Principles

- Pertussis remains a cause of high morbidity and mortality among children worldwide.
- Widespread use of pertussis vaccine in the United States since the late 1940s has reduced the number of reported pertussis cases and deaths by 98 percent. The estimate of children vaccinated with three or more doses of pertussis vaccine has exceeded 90 percent since 1994.[5]However, despite steady coverage levels of vaccine among preschool children[6]and mandatory vaccination among school-age children, pertussis remains endemic in the United States. In 2012, 32,680 cases of pertussis were reported to the Centers for Disease Control and Prevention (CDC).[7]
- Although cyclic, pertussis is increasing with the highest rates occurring among young infants and adolescents. Waning immunity approximately 5 to 10 years after booster vaccination increases susceptibility among adolescents and adults.[8]Improvement in laboratory testing and increased reporting may be contributing to the increased numbers of cases reported in adolescents and adults.[8,9]

History of the Disease

Pertussis was first recognized in the 16th century.[10]The name accurately describes the disease (*per*, meaning intensive or pernicious, and *tussis*, meaning cough).[11]Cherry,[10]in a comprehensive historical review, noted that a disease consistent with pertussis (although given another name) was first mentioned in England in 1540. An outbreak with symptoms also consistent with pertussis occurred in 1578 in Paris. It was Sydenham who first gave the illness the name "pertussis" in 1679. Not until 1900 did Bordet and Gengou observe the causative organism (obtained from sputum) under a microscope. Because of the difficulties encountered while attempting to grow the organism, it would take another 6 years to actually isolate it.

Epidemiology and Transmission

Pertussis outbreaks among adolescents and adults, including healthcare personnel, are increasingly reported. A pertussis outbreak occurred among adults at an oil refinery in Illinois in August to October

2002.[12]A countywide pertussis outbreak occurred in 2003 that was associated with users of a high school weight room.[13]In 2004, a tertiary care center reported two pertussis outbreaks, one community based, and one associated with infected healthcare personnel.[14]An outbreak among newborns in 2004 was determined to be the result of direct exposure to a healthcare provider with pertussis.[15]In 2005, an outbreak of pertussis occurred among adolescents at a military community.[16]All of these outbreaks reinforce the need for healthcare providers to recognize that asymptomatic and subclinical infections are common in adolescents and adults.[17,18]Even when a cough is present, pertussis is often overlooked in the differential diagnosis in adolescent and adult patients. Other etiologic agents of cough illness that should be ruled out include adenoviruses, *Mycoplasma pneumoniae, Chlamydia pneumoniae*, and respiratory syncytial virus.[19]Incidence rates of pertussis are reported to have increased 400 percent during the period 1990 to 2001, with approximately 50 percent of cases found in adolescents (aged 10 to 19 years) and adults (aged ≥20 years).[12]Exposure to unrecognized cases of pertussis in adolescents and adults may provide an explanation as to the increase of pertussis seen in susceptible children.[20,21] Infants, particularly those younger than 6 months of age, are at highest risk for pertussis and its complications (pneumonia, seizures, encephalopathy, and death).[22,23]

Historically, epidemics of pertussis have been found to be cyclic, occurring every 2 to 5 years. Studies of pertussis in adults suggest that immunity following *B. pertussis*vaccination is not lifelong and that reinfection is common in both previously vaccinated and nonvaccinated persons.[20]As a result, the increased incidence among adolescents and adults that has been reported[9,12,24,25]may play an important role in the transmission of pertussis to susceptible infants.[26]Immunity from childhood vaccination wanes 5 to 10 years after the last whole-cell vaccine dose (usually given at 4 to 6 years of age). Twelve years after the last dose of vaccine, there was almost no residual protection. The efficacy of the whole-cell diphtheria-tetanus-pertussis (DTP) vaccine, no longer used in the United States, was estimated to be between 70 and 90 percent.[27]

Because pertussis is so highly contagious, secondary attack rates may exceed 80 percent among susceptible household contacts.[28]Transmission occurs by direct contact with respiratory secretions or large aerosol droplets from the respiratory tract of infected persons. The period of communicability starts with the onset of the catarrhal stage and extends into the paroxysmal stage[19](Figure 71-1).

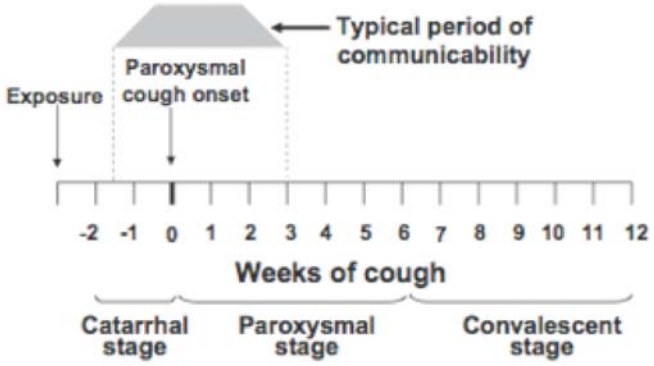

Figure 71-1.

Period of communicability of pertussis. (From Bisgard K. Background. In: *Guidelines for the Control of Pertussis Outbreaks*. Atlanta, GA: Centers for Disease Control and Prevention; 2000. Used with permission.) View Image

It is important to recognize that pertussis is truly a worldwide disease that has no boundaries. Even with a global vaccination level of approximately 80 percent in 1999, an estimated 48.5 million pertussis cases occurred in children

worldwide.[29]There were an estimated 295,000 deaths that year, occurring mostly in Africa. This is not surprising because incidence and mortality rates are closely tied to the presence of immunization programs, good nutrition, and the availability of quality medical care. Countries in which documented immunization rates have fallen have experienced an increase in incidence rates (Japan, Sweden, and United Kingdom).[30]Decreased immunization rates may also pose a potential problem during a disaster if the disease occurred in crowded refugee camps.[29]

Diagnosis

The gold standard methodology for the laboratory diagnosis of pertussis is culture, utilizing either fresh Bordet-Gengou or Regan-Lowe media. The specimen of choice is a nasopharyngeal aspirate or swab (calcium alginate or polyethylene terephthalate). If direct inoculation of the medium is not possible, specimens must be placed in Regan-Lowe transport medium (one-half strength charcoal agar supplemented with horse blood and cephalexin) and stored at 4ºC until processed.[3,31,32]The sensitivity of culture has been reported to range from 15 to 80 percent, with lower performance if the patient has begun a regimen of effective antibiotic therapy (erythromycin, trimethoprim-sulfamethoxazole, azithromycin, or clarithromycin) or if the specimen is obtained more than 3 weeks after onset of cough.[33]

Direct fluorescent antibody (DFA) testing may be also used to diagnose pertussis infection. The test is highly specific at 98 percent. The sensitivity has been reported at 52 percent. Due to this low sensitivity, culture confirmation should be attempted if DFA testing is performed.[33,34]

Polymerase chain reaction (PCR) tests for identification of *B. pertussis*are now rapid and specific, with a higher sensitivity than either culture or DFA.[33,34,35,36,37]It is important that calcium alginate swabs should not be used for nasopharyngeal collection if PCR testing will be performed because they have been shown to be inhibitory.[31]PCR, despite being labor intensive,[38]has been used as a rapid method to document healthcare-associated cases of pertussis.[39]Enzyme-linked immunosorbent assay (ELISA) techniques to identify serum antibodies to pertussis are another option for diagnosis if acute and convalescent sera are available.[19,28,31]

Cases may be classified as "probable" or "confirmed" based on laboratory findings. The pertussis case definition developed and adopted by the Council of State and Territorial Epidemiologists (CSTE) and the Centers for Disease Control and Prevention (CDC) defines a clinical case of pertussis as a cough illness lasting 2 weeks or more with paroxysms of coughing, inspiratory "whoop," or posttussive vomiting without other apparent cause. (In outbreak settings, a case may be defined as a cough illness lasting ≥2 weeks.) The laboratory criteria for diagnosis are isolation of *B. pertussis*from clinical specimen or positive PCR for *B. pertussis*. Cases are further classed as "probable," in which the case meets the clinical case definition but is not laboratory confirmed and is not epidemiologically linked to a laboratory-confirmed case, or, "confirmed," in which the case is laboratory confirmed or one that meets the clinical case definition and is epidemiologically linked to a laboratory-confirmed case.[9,40]

Clinical Manifestation

The incubation period of pertussis in nonimmunocompromised patients is usually 7 to 10 days, with a range of 6 to 21 days. Rarely, the incubation period may be as long as 42 days. Classically, the onset, known as the catarrhal stage, is insidious with symptoms similar to that of the common cold: coryza (runny nose), sneezing, low-grade fever, and a mild, occasional cough that gradually becomes more severe. This stage lasts 1 to 2 weeks. The cough that began during the catarrhal stage progresses steadily, becoming paroxysmal (numerous, rapid coughing). It is during this second paroxysmal stage that the diagnosis of pertussis is usually suspected. The patient appears well between bouts of coughing, and if no paroxysm of coughing occurs during the physical examination, the diagnosis may be missed. The classic symptoms of pertussis include whoop, vomiting, apnea, and cyanosis immediately after a paroxysm of coughing. Infants younger than 6 months may have an atypical presentation with a short catarrhal stage, gagging and gasping, or apnea as prominent early manifestations. The "whoop" may be absent.[31]Paroxysmal attacks occur more frequently at night, with an average of 15 attacks per 24 hours.[41]The paroxysmal stage lasts 1 to 6 weeks but may persist for as long as 10 weeks. During the convalescent stage, the cough becomes less paroxysmal and gradually disappears. This stage may persist for many months, particularly during subsequent viral upper respiratory tract infections that may cause paroxysms. Symptoms of pertussis are milder in vaccinated persons, and the diagnosis may be missed in adolescents and adults, who often have less characteristic symptoms (Table 71-1).

Table 71-1 Signs and Symptoms of Pertussis

Signs and Symptoms	Adults**	Children ≤24 Months†
Paroxysmal cough	15 (94 percent)	118 (65 percent)
Sputum production	12 (75 percent)	
Awakened by cough	14 (88 percent)	
Cough-induced vomiting	5 (31 percent)	116 (64 percent)
Whoop		18 (10 percent)
Cyanosis with cough		108 (59 percent)
Convulsion*		9 (5 percent)
Fever		61 (34 percent)
Apnea		45 (25 percent)
Cyanosis		108 (59 percent)

*A total of 11 patients (6 percent) had one or more convulsions.

†Gan VN, Murphy T. Pertussis in hospitalized children. *Am J Dis Child*1990;144(10):1130–1134.

Pathogenesis

The pathogenesis of pertussis is complex. The organism attaches to ciliated epithelial cells in the respiratory tract. As mentioned, *B. pertussis*produces a number of biologically active substances that are thought to play a role in attachment to respiratory epithelium (pertussis toxin, filamentous hemagglutinin, pertactin, agglutinogens), cell toxicity (pertussis toxin, tracheal cytotoxin), and disruption of the host immune response (pertussis toxin and adenylate cyclase). These antigens evade the host defenses; thus, one sees lymphocytosis and impaired chemotaxis.[2]Of these, pertussis toxin is thought to be of major importance. Pertussis toxin prevents migration of lymphocytes to areas of infection and adversely affects phagocytosis and intracellular killing. It also affects glucose metabolism, resulting in a mild, compensated hyperinsulinemia.[42]Antibodies to pertussis toxin are usually found after natural disease and vaccination; however, no serologic correlate of clinical protection has been identified.

Treatment and Postexposure Prophylaxis

In 2005, the CDC issued guidelines for recommended antimicrobial agents for the treatment and postexposure prophylaxis of pertussis (Table 71-2).[43]The macrolide agents erythromycin, clarithromycin, and azithromycin are preferred for the treatment of pertussis in persons 1 month of age and older. For infants younger than 1 month, azithromycin is preferred; erythromycin and clarithromycin are not recommended. For treatment of persons aged 3 months of age and older, an alternative agent to macrolides is trimethoprim-sulfamethoxazole (TMP-SMZ).

Table 71-2 CDC Recommendations for Treatment/Prophylaxis of Pertussis

Age Group	Primary Agents	Alternate Agent*		
Azithromycin	Erythromycin	Clarithromycin	TPM-SMZ	
<1 month	Recommended agent. 10 mg/kg per day in a single dose for 5 days (only limited safety data available)	Not preferred. Erythromycin is associated with infantile hypertrophic pyloric stenosis. Use if azithromycin is unavailable; 40–50 mg/kg per day in four divided doses for 14 days	Not recommended (safety data unavailable)	Contraindicated for infants aged <2 months (risk for kernicterus)
1–5 months	10 mg/kg per day in a single dose for 5 days	40–50 mg/kg per day in four divided doses for 14 days	15 mg/kg per day in two divided doses for 7 days	Contraindicated at age <2 months. For infants aged ≥2 months, TMP 8 mg/kg per day, SMZ 40 mg/kg per day in two divided doses for 14 days
Infants (aged ≥6 months) and children	10 mg/kg in a single dose on day 1 then 5 mg/kg per day (maximum: 500 mg) on days 2–5	40–50 mg/kg per day (maximum: 2 g per day) in four divided doses for 14 days	15 mg/kg per day in two divided doses (maximum: 1 g per day) for 7 days	TMP 8 mg/kg per day, SMZ 40 mg/kg per day in two divided doses for 14 days

Adults	500 mg in a single dose on day 1 then 250 mg per day on days 2–5	2 g per day in four divided doses for 14 days	1 g per day in two divided doses for 7 days	TMP 320 mg per day, SMZ 1600 mg per day in two divided doses for 14 days

*Trimethoprim-sulfamethoxazole (TMP-SMZ) can be used as an alternative agent to macrolides in patients aged ≥2 months who are allergic to macrolides, who cannot tolerate macrolides, or who are infected with a rare macrolide-resistant strain of *Bordetella pertussis*.

For postexposure prophylaxis, a macrolide can be administered if the person has no contraindication to its use.

Pertussis symptoms may be greatly diminished when effective antimicrobial therapy is started during either the catarrhal stage or within 2 weeks of cough onset.[31] However, once the paroxysmal stage has begun, antimicrobial therapy has little effect on the course of illness and is indicated primarily to limit the spread of the organism to others. Patients are no longer infectious after 5 days of effective therapy.

Outbreaks

Transmission of pertussis in hospital settings has been documented in numerous reports (Table 71-3). Recent outbreaks cost estimates vary from just over $80,000 to more than $200,000. Cost estimates typically include testing, prophylaxis, and labor costs. At a tertiary healthcare facility with adult and pediatric beds, 17 symptomatic cases of pertussis were identified among healthcare personnel (HCP) resulting from a 1-day exposure. The total measured cost of that outbreak to the hospital was $81,382, including costs incurred by the HCP of $6,512.[44] Another tertiary facility experienced two outbreaks. The first was community based, but the second involved many HCP. There was documentation of transmission of pertussis from patients to HCP, but no documentation of transmission from HCP to patients. Costs associated with the second outbreak were $236,284.

Hospital outbreaks have resulted from failure to recognize and isolate infected infants and children, failure to recognize and treat disease in staff members, and failure to rapidly institute control measures.[45] Either HCP or a patient may introduce *B. pertussis* into the hospital or clinic, and subsequent transmission to patients or HCP (or both) may occur. The risk of developing pertussis for patients or staff during these outbreaks is often difficult to quantify because the definition of what constitutes exposure continues to be refined.

Transmission of pertussis to susceptible contacts living in the same household is a common occurrence. A case of pertussis should be immediately reported to local health department authorities to facilitate identification and antibiotic treatment or prophylaxis of household contacts.[31]

Prevention

CURRENT ADVISORY COMMITTEE ON IMMUNIZATION PRACTICES RECOMMENDATIONS

Infants and Children

The Advisory Committee on Immunization Practices (ACIP) recommends a licensed acellular pertussis vaccine (DTaP), containing diphtheria, tetanus toxoids, and acellular pertussis vaccines for all five doses of the routine diphtheria, tetanus, and pertussis vaccination series and for the remaining doses in the series for children who have started the vaccination series with whole-cell DTP vaccine (no longer available in the United States). The primary series of DTaP consists of four doses of vaccine. The first three doses are given at 4- to 8-week intervals (with a minimum of 4 weeks between) beginning at 6 weeks to 2 months of age. The fourth dose is given 6 to 12 months after the third. If the child received all four primary doses before turning 4 years old, a fifth (booster) dose should be given before the child enters school. ACIP also notes that interruption of the recommended schedule, or delayed doses, does not lead to a reduction in the level of immunity reached on completion of the primary series. There is no need to restart a series regardless of the time that has elapsed between doses.[31]

Table 71-3 Outbreaks of Pertussis in Hospital Settings Indicating Number of Patients and Staff With Clinical Disease and Impact of Outbreak

Author	Setting	Clinical Pertussis	Interventions	Cost		
No. of Patients	No. of Staff	No. Screened				
Calugar et al.[44]	Tertiary care with adult and pediatric beds		17	307 close contacts of those staff	184 lab tests; 324 treatment and prophylaxis; 725 labor hours; 808 letters distributed; 560 administrative leave hours	$6512 for healthcare personnel$81,382 total costs
Zivna et al.[25] Shefer et al. (1995)	Tertiary care medical center/affiliated ambulatory care settings 800-bed hospital	189	210	353 staff	287 employees received treatment/prophylaxis; erythromycin for 350 patients and 40 staff; 630 staff vaccinated	Total cost $85,066–$98,456 Not noted

Baggett et al. (2007) Wiblin et al.**54**	(A) 500-bed tertiary care hospital (B) 250-bed pediatric hospital (C) 640-bed hospital	3	7 513	738 (388 staff, 256 patients, 85 visitors) 737 (417 staff, 120 patients, 200 visitors)	187 laboratory tests; 516 treated 120 laboratory tests; 413 treated; 298 employees and 60 patients had face-to-face exposure; erythromycin for all high-risk persons	$263,357 $121,130 $4357 for prophylaxis alone
Leekha, Thompson, & Sampathkumr[14a] Zivna et al.**25**	2,036-bed tertiary care center with two outbreaks Tertiary care medical center/ affiliated ambulatory care settings	97 first outbreak 58 second outbreak 18	12 first outbreak 64 second outbreak 2	2,337 first outbreak 1,976 second outbreak 353 staff	287 employees received treatment/prophylaxis	Not measured in first outbreak $236,284 second outbreak Total cost $85,066–$98,456
Baggett et al. (2007)	(A) 500-bed tertiary care (B) 250-bed pediatric hospital		7 5	738 (388 staff, 256 patients, 85 visitors) 737 (417 staff, 120 patients, 200 visitors)	187 laboratory tests; 516 treated 120 laboratory tests; 413 treated	$263,357 $121,130
Leekha, Thompson, & Sampathkumr[14a]	2,036-bed tertiary care center with two outbreaks	97 first outbreak 58 second outbreak	12 first outbreak 64 second outbreak	2,337 first outbreak 1,976 second outbreak		Not measured in first outbreak $236,284 second outbreak

Recommendations for vaccination of adolescents have also been issued. Adolescents 11 to 18 years of age should receive a single dose of Tdap (containing tetanus toxoids, reduced diphtheria toxoids, and acellular pertussis).[46]

Children age 7 to 10 years that are not fully vaccinated against pertussis should receive a single dose of Tdap.[47]

Pregnant Women

The current ACIP recommendation is to vaccinate pregnant women with Tdap during every pregnancy, regardless of the patient's prior Tdap vaccination history, to provide the highest concentration of maternal antibodies to the infant. If Tdap is not administered during pregnancy, it should be administered immediately postpartum.[48]

In 2007, Dylag and Shah[49]conducted a study combining several of these recommendations. Within their level III neonatal intensive care unit (NICU), eligible parents were offered the Tdap vaccine. Of the 495 parents offered the vaccine (82.8 percent of the 598 eligible parents), 86.9 percent (430 parents) received the vaccine. The remaining 11.1 percent of the parents who refused the vaccine either thought pertussis was not a significant health threat or did not believe in vaccination. Based on the results of this study, the NICU appears to be an excellent place to immunize parents and perhaps other close contacts of neonates who are at high risk.

All Other Adults

ACIP recommends that all adults aged 19 years and older that have not received a dose of Tdap should receive a single dose, regardless of the interval since their last tetanus or diphtheria toxoid-containing vaccine.[47,50]

At this time, other than in pregnant women, ACIP is not making recommendations regarding revaccination of adults with Tdap. This is still being evaluated and is expected to be addressed in the future.

Risk Reduction

The CDC and prevention and infectious disease experts recommend the following guidelines for managing pertussis exposures.[50,51,52,53]

- Implement Droplet Precautions in addition to Standard Precautions for suspected or known infected patients.
- Cohort exposed patients.
- Provide postexposure prophylaxis for all asymptomatic exposed employees, patients, and visitors regardless of immunization history.
- Evaluate all symptomatic employees for pertussis and provide appropriate antimicrobial therapy.
- Furlough symptomatic employees during the first 5 days of their therapy.

More expansive measures are indicated when extensive outbreaks extend from the community into the healthcare institution.[43]These include:

- Educate continuously with in-services on high-risk units and via hospital newsletters, and educational fact sheets, fax network to community physicians, and the news media.
- Distribute standardized checklists, forms, and guidelines developed by the infection preventionist (IP).
- Engage IPs to assist with management of the exposures.
- Evaluate employees for respiratory symptoms and illness.

- Institute Isolation Precautions for patients admitted with suspected pertussis.
- Cohort patients displaying classic symptoms of coughing, etc.
- Consider requiring all visitors to wear surgical masks while in the affected facility.
- Restrict inpatients to the assigned unit. Consider masking inpatients if they leave the unit.
- Limit or restrict facilitywide visitors and consider placing security officers at elevators.
- Provide inpatient sibling and employee day care but do not allow symptomatic children.
- Consider providing acellular pertussis vaccination for exposed staff.

It should be noted that the use of vaccines for HCP, even during outbreak situations, remains a matter of controversy, and is not currently recommended by the ACIP. Early diagnosis of pertussis before secondary transmission occurs is difficult because pertussis is highly communicable in the catarrhal stage, when symptoms are still nonspecific. Pertussis should be one of the differential diagnoses for any patient with an acute cough illness lasting 7 days or more without an apparent cause, particularly if accompanied by paroxysms of coughing or vomiting after coughing, whoop, or apnea. Nasopharyngeal cultures or PCR should be obtained whenever possible.

Patients admitted to the inpatient facility or undergoing outpatient evaluation with suspected or confirmed pertussis should be placed on Droplet Precautions to prevent spread of infection (private room, mask for personnel entering the room, mask on patient when traveling in the hospital). Droplet Precautions should continue until the condition is clinically improved and the patient has received at least 5 days of appropriate antimicrobial therapy.

Relieve symptomatic HCP (e.g., unexplained rhinitis or acute cough) with known pertussis exposure from work activities within healthcare settings. A nasopharyngeal specimen should be obtained for *B. pertussis*culture or PCR and appropriate antimicrobial therapy initiated. Return to work is permitted after completing at least 5 days of antimicrobial therapy. HCP with known pertussis exposure who are asymptomatic need not be excluded from duty but should receive antimicrobial prophylaxis as soon as possible.

The approach to postexposure prophylaxis for HCP (shown in Table 71-2) is the same as for treatment of pertussis. Because the nature and duration of exposure sufficient for transmission of pertussis are unknown, the following guidelines may be used by IPs to determine eligibility for prophylaxis with a minimum amount of confusion. Of primary importance is that for transmission to occur, the source case must truly have pertussis, and the nature and duration of contact must be evaluated. The source case should be documented to have pertussis in one of the following ways: (1) proven by culture; (2) an acute cough illness for 14 days or longer with at least one associated symptom (paroxysmal cough, posttussive vomiting, or whoop) and supportive laboratory evidence of pertussis infection (DFA testing, positive serologic findings, or PCR); or (3) clinically consistent illness as described immediately preceding and an epidemiologic link to a culture-positive case.

Transmission requires close contact with respiratory secretions without having worn respiratory protection devices. Close contact includes unprotected face-to-face contact with a patient who is symptomatic (e.g., in the catarrhal or paroxysmal period of illness); sharing a confined space in close proximity for a prolonged period of time (e.g., 1 hour or more) with a symptomatic patient; or direct contact with respiratory, oral, or nasal secretions from a symptomatic patient (e.g., an explosive cough or sneeze on the face, sharing food, sharing eating utensils during a meal, kissing, mouth-to-mouth resuscitation, suctioning, intubation, bronchoscopy, or performing a full medical examination of the nose and throat).[54]Because neonates and young infants are at highest risk of severe disease and

complications from pertussis, a more conservative definition of contact may be used for such patients (e.g., being in an enclosed room with a documented case for 1 hour or longer or shorter if the infant is being held).

Conclusions

Despite widespread use of pertussis vaccines in the United States since the late 1940s, pertussis remains endemic in the United States. It is also possible that the accuracy of diagnosis and reporting of illness to public health authorities, along with the cyclic nature of the disease, may be contributing to the apparent increase in the number of cases in recent years. Healthcare providers must recognize that asymptomatic and subclinical infections are common in adolescents and adults and that pertussis is often overlooked in adult patients. Exposure to unrecognized cases of pertussis in adolescents and adults may provide an explanation as to the increase of pertussis seen in susceptible children. Infants, particularly those younger than 6 months, are at highest risk for pertussis and its complications (pneumonia, seizures, encephalopathy, and death).

Reinfection is common in previously vaccinated and nonvaccinated individuals. Immunity from childhood vaccination wanes 5 to 10 years after the last vaccine dose (usually given at 4 to 6 years of age), and by 12 years after the last dose of vaccine there is almost no residual protection. Currently, the ACIP recommends a licensed DTaP (combination diphtheria, tetanus toxoids, and acellular pertussis vaccines) for all five doses of the routine diphtheria, tetanus, and pertussis vaccination series and for the remaining doses in the series for children who have started the vaccination series with whole-cell DTP vaccine.

Future Trends

As vaccine recommendations are updated and target groups are expanded, it will be important to assess the effectiveness. As more data become available regarding waning vaccine protection as well as data supporting the safety of multiple vaccines, additional boosters in adults may be able to address this issue. In the meantime, early detection remains a key factor in prevention. Educating providers not only to consider pertussis, but also to employ Droplet Precautions early in a patient encounter will mitigate exposures. For the most current information on pertussis access the CDC website on pertussis at **http://www.cdc.gov/pertussis/**.

International Perspective

Pertussis represents a global health issue with a significant impact on the health of children in developed and undeveloped countries. With struggling public health infrastructures and inconsistent or absent immunization programs, continued epidemics of this and other vaccine-preventable diseases can be expected. Global travel also aids in the transmission of pertussis to susceptible populations.

APIC TEXT OF INFECTION CONTROL AND EPIDEMIOLOGY

Clostridium difficile Infection and Pseudomembranous Colitis

Author(s): Jason E. Bowling, MD
Assistant Professor

Department of Medicine/Division of Infectious Diseases

Published: October 3, 2014

Abstract

Clostridium difficile*is a Gram-positive, spore-forming anaerobic bacillus that produces two large toxins, A and B, which cause diarrhea and colitis in susceptible patients whose normal colonic bacterial flora has been previously disrupted by prior antimicrobial treatment. Rates of* C. difficile *infection in the United States have tripled since the year 2000, mortality has increased, and a toxin variant strain of* C. difficile*known as BI/NAP1/027 has become widespread in North America and Europe. Pseudomembranous colitis is seen in about half the patients with symptomatic* C. difficile*infection and is characterized by formation of punctate pseudomembranes that can cover the entire colonic surface in severe cases. High-risk environments include acute care hospitals and long-term care facilities in which the use of antimicrobials is high (increasing the size of the susceptible population) and the environment is heavily contaminated by the spores of* C. difficile *(increasing the risk of patient contact with the organism). Good personnel hand hygiene, gloving, barrier precautions, and thorough environmental cleaning to prevent transmission of the spores to the patient can accomplish prevention and control.* C. difficile*infection also can be prevented by reducing overall antimicrobial usage and by avoiding use of certain specific antimicrobials, such as clindamycin, third-generation cephalosporins, and fluoroquinolones. Treatment is with another antimicrobial agent, either metronidazole (first choice for mild to moderately severe disease) or oral vancomycin (first choice for severe* C. difficile*infection).*

Key Concepts

- Patient susceptibility to *Clostridium difficile*infection requires prior antimicrobial treatment.

- Healthcare personnel transmit *C. difficile* on their hands.
- *C. difficile* spores may contaminate the healthcare environment.
- Patients asymptomatically colonized with *C. difficile* are at reduced risk of infection.
- Barrier precautions can be used to prevent *C. difficile* from reaching the patient.
- Thorough environmental cleaning reduces spore contamination and *C. difficile* infection incidence.
- Effective antimicrobial stewardship can effectively reduce *C. difficile* infection rates.

Background

Clostridium difficile infection (CDI) is an infectious bacterial diarrhea that occurs almost invariably in patients who have taken antibiotics recently (usually within 2 months). It was previously believed that the responsible organism, *C. difficile*, is part of the normal flora and proliferates to cause disease when antibiotics are given. Several studies suggest that this is an incorrect hypothesis and that patients who are colonized asymptomatically with *C. difficile* are at decreased, not increased, risk of CDI compared with patients in the same hospital environment who are not previously colonized with *C. difficile*.[1]

Pseudomembranous colitis (PMC) is a more severe form of CDI in which patients exhibit a colitis characterized by the presence of pseudomembranes on the colon surface. The colonic mucosa shows punctate-to-confluent, yellow, white, or gray plaques that are readily visualized at endoscopy, but are observed in only about half of all patients with symptomatic CDI. Biopsy specimens show a neutrophilic mucosal infiltrate beneath the necrotic plaques or pseudomembranes.

It has been shown that *C. difficile*, a Gram-positive, spore-forming anaerobic organism, causes disease by producing two large toxins, toxin A (an enterotoxin and cytotoxin) and toxin B (a cytotoxin). A third toxin, known as binary toxin, has been found in about 5 percent of *C. difficile* isolates and in 100 percent of the BI/NAP1/027 epidemic strain. The ability of the organism to produce spores enables *C. difficile* to survive for months in the environment of healthcare institutions, from which it is spread by transfer of spores directly from the contaminated environment to the patient or by transfer on the hands of healthcare personnel (HCP) who fail to follow good hand hygiene and gloving practices. It is generally accepted that any hospitalized patient can acquire the *C. difficile* organism, but for CDI to occur, it is necessary for the patient to have received antimicrobials (that disrupt the normal bacterial flora). Certain cancer chemotherapeutic agents (which also have antibiotic activity) also place patients at risk.[2,3,4,5,6]

Basic Principles

CDI is one of the most common and costly healthcare-associated infections (HAIs). Understanding its unique epidemiological association with prior antimicrobial treatment is key to learning the best methods of prevention, control, and treatment. The difficulty of eliminating *C. difficile* spore contamination of the hospital environment can be best understood by considering the extreme measures that federal agencies have taken in decontaminating buildings after the anthrax spore contamination of mail centers and office buildings.

Trends

Several trends are evident with regard to CDI. The rate of disease has been increasing in hospitals in the United States, Canada, and Europe. Third-generation cephalosporins have supplanted clindamycin as the highest risk antimicrobials associated with CDI.[7] Association with the use of fluoroquinolone antimicrobials is an emerging trend. A cohort study found fluoroquinolone use to be the most important risk factor for CDI during an epidemic.[8] An epidemic strain of *C. difficile* designated BI/NAP1/027 that produces high levels of toxins A and B, possesses a third toxin—binary toxin, which is highly resistant to fluoroquinolone antibiotics–and has spread widely throughout North America and Europe with associated high mortality and morbidity.[9,10]

Epidemiology

CDI attack rates vary widely from hospital to hospital and within hospitals over time. Rates ranging from less than 1 per 1,000 discharges to more than 25 per 1,000 discharges have been observed. Because the at-risk population is limited essentially only to patients who receive antimicrobials, the actual rates per at-risk patient are more than twice as high, as only about half of hospitalized patients receive antimicrobials.

Employee hands and a variety of environmental sites have been found to be contaminated with *C. difficile* spores, the latter in proportion to the status of the patient in the room; environmental rates of contamination are highest if the patient in the room has active CDI with diarrhea, intermediate if the patient is asymptomatically carrying *C. difficile*, and low if the patient does not have *C. difficile* in the stool. Commodes, baby baths, and electronic thermometer handles are among the environmental sites implicated in the transmission of *C. difficile*.[2,4]

Through the use of many genetic typing methods, *C. difficile* outbreaks have been shown to be caused predominantly by single strains, supporting the hypothesis that the majority of CDI is transmitted within the healthcare facility.[2,3,9,11] Some hospitals also have documented a wide variety of strains causing disease simultaneously and have shown the presence of *C. difficile* in the stools of some patients at the time of admission, particularly if the patient was recently hospitalized. Uncolonized patients have been shown to acquire *C. difficile* at a linear rate of about 8 percent per week in high-incidence hospitals, but most patients remain asymptomatic even if they acquire a toxigenic strain.[12] It has been shown that patients who become asymptomatically colonized with *C. difficile* are at decreased risk of CDI.[1] About 40 percent of *C. difficile* strains in hospitals lack the genes to produce toxins A and B and are considered nontoxigenic and harmless to patients. If a patient acquires one of these strains, he or she is not at risk for developing CDI. A patient who acquires a toxigenic strain of *C. difficile* is protected from getting CDI if he or she is able to develop a rapid anamnestic serum immunoglobulin G (IgG) antibody response to toxin A.[13] Patients who fail to develop an anamnestic antibody response develop CDI and are at increased risk of a recurrence of CDI if they fail to develop antibody during the course of their illness.[14]

Some hospitals may observe a predominant single strain of *C. difficile*, whereas others have a wide diversity of strains causing CDI.[3,13,14,15] Data on asymptomatic carriage and rates of acquisition of *C. difficile* in hospitals with low rates of CDI are not known. Based on rectal swab culture data, most healthcare-associated CDI is the result of acquisition and infection with *C. difficile* organisms acquired in the hospital, rather than from organisms that colonized the patient before hospitalization. Other risk

factors include prolonged hospital stay, advanced age, and intestinal tube feedings.[6,16,17] Normal humans in most studies have only a 1 to 3 percent rate of asymptomatic stool colonization with *C. difficile*, whereas patients with colonoscopy-proven PMC generally have a 90 percent or greater rate of presence of *C. difficile* or its toxin. There is an important exception, however: 50 percent of infants through about 1 year of age harbor the organism and its toxin without any gastrointestinal tract symptoms. In addition, it is well known that 20 percent of hospitalized patients of all ages asymptomatically carry toxigenic and nontoxigenic strains of *C. difficile* in their stool.[2,3]

Clinical Features

Diarrhea is the most common clinical symptom of CDI. It is almost never grossly bloody and ranges in consistency from soft unformed stools to watery or mucoid and in frequency from 3 to 20 or more bowel movements per day.[6] Some HCP who are experienced in caring for these patients are able to distinguish a characteristic fecal odor. Clinical symptoms include abdominal pain and cramping (22 percent of patients) and fever (28 percent of patients).[6] Laboratory findings include leukocytosis (>10,000 white blood cells/mm^3) in 50 percent of patients, at times greater than 40,000 white blood cells/mm^3, and occult fecal blood in 26 percent of patients.[6]

Patients who develop an ileus are at especially high risk of fulminant CDI and complications of *C. difficile*, particularly toxic megacolon and perforation of the colon. Toxic megacolon complicating *C. difficile* diarrhea occurred in 3.1 percent of patients in one hospital and resulted in 64 percent mortality. Overall mortality in the past was usually low in patients with CDI because of the excellent response to treatment. Mortality ranged from 0.6 to 3.5 percent of patients seen at two hospitals in a 10-year period; however, in hospitals experiencing outbreaks with the BI/NAP1/027 strain of *C. difficile*, 30-day attributable mortality was 6.9 percent. Elderly patients are at highest risk for mortality and the older the patient the higher the risk of death with CDI.

Extracolonic manifestations of *C. difficile* infection are rare. Reactive arthritis, usually involving large joints, has been described, as has ascites. *C. difficile* has been isolated from body sites other than stool, including joint fluid, blood, peritoneal fluid, splenic abscess, and ascites, but these are rare events.

Recurrence of *C. difficile* diarrhea after treatment occurs in 15 to 25 percent of patients. The term recurrence rather than relapse is preferred because about 40 percent of patients have recurrences that are not caused by the original organism and are not relapses, but rather are reinfections with a new strain of *C. difficile*. Recurrence does not correlate with continued isolation of the organism from stool after treatment, which occurs commonly. The risk factors for recurrence are increased age, decreasing quality-of-life score, continued hospitalization, and failure to develop an anamnestic or recall serum antibody response to toxin A.[12]

Diagnosis

Diagnostic studies for CDI should be performed only on patients who are symptomatic. The usual symptom is diarrhea. The presence of three or more unformed or watery stools in a 24-hour period in a hospitalized patient is sufficient indication to submit a specimen for *C. difficile* testing. Studies on asymptomatic patients should be conducted only for epidemiological purposes, not as a "test of cure"

after treatment or to identify carriers for treatment because it has been shown that carrier treatment is usually futile, and the presence of toxin or the organism in stool after successful treatment does not predict which patients will have recurrence of CDI.[18,19] There are many diagnostic tests for CDI available, each with different advantages and disadvantages.

STOOL CULTURE

C. difficile is readily recovered from stool using cycloserine-cefoxitin-fructose agar selective medium. Placing the plates in an anaerobic environment for at least 4 hours to reduce (remove oxygen from) them before inoculation markedly enhances the culture yield. Culture is the most sensitive test of stool available, but has some false-positive results due to the presence of nontoxigenic *C. difficile* isolates; confirmation of toxin production in vitro is recommended to be certain the isolate is toxigenic.[18] It is generally considered the "gold standard" for CDI diagnostic tests because of its sensitivity but the turnaround time of 7 days prevents it from being employed in the clinical setting.[20]

CELL CYTOTOXICITY ASSAY

C. difficile toxin may be detected by adding stool extract with and without neutralizing antitoxin to cell culture monolayers. The toxin is presumed to be present if a cytotoxic effect is produced by stool extract but is prevented by the addition of specific neutralizing antitoxin. This is the most specific test for CDI but is not as sensitive as stool culture for toxigenic *C. difficile*.[18] This assay is labor intensive, requires a skilled reader, and has a turnaround time of up to 72 hours from sample receipt.[20]

ENZYME IMMUNOASSAY FOR TOXINS A AND B

Enzyme immunoassays are commercially available that use monoclonal antibodies to detect toxin A and usually polyclonal antibodies to detect toxin B. They are generally rapid and specific and conserve technical time, but are less sensitive than the cell cytotoxicity assay. More recent studies indicate that these assays do not have appropriate sensitivity to be used as an independent diagnostic test for CDI.[20]

LATEX TEST OR ENZYME IMMUNOASSAY FOR *C. DIFFICILE* ANTIGEN

The latex test initially was developed to detect *C. difficile* toxin A but actually detects another antigen, glutamate dehydrogenase (GDH). The latex test is less sensitive and less specific than other tests and does not give information about the presence of toxin.[18] Use of this test as the sole test for diagnosis of CDI should be discouraged. When testing for GDH is done by enzyme immunoassay, the sensitivity is improved, although specificity is poor because GDH is found in both toxigenic as well as nontoxigenic *C. difficile*, as well as in other organisms. The GDH enzyme immunoassay has been used as the first step in a two-step testing algorithm, suggesting that negative GDH specimens can be eliminated from further testing; however, this observation may not be valid if the sensitivity of the GDH assay is not sufficiently high.[21,22]

COLON ENDOSCOPY

Flexible sigmoidoscopy, proctoscopy, and colonoscopy all can be used to detect PMC and are the only means to detect PMC other than surgery or autopsy. These modalities are insensitive in the detection of CDI, however, because results of endoscopy (visualization of PMC) are positive in only about 50 to 55 percent of patients who have diarrhea and whose stools are positive in the cell cytotoxin test and

positive for *C. difficile* by culture.[6] Also, endoscopic procedures entail certain potential risks to the patient and are expensive. The American College of Gastroenterology provides specific recommendations for use of endoscopy in CDI diagnosis to include the need for a rapid diagnosis with an expected delay in laboratory testing or the inability to obtain stool specimen because of ileus.[20]

NUCLEIC ACID AMPLIFICATION TESTS

Nucleic acid amplification tests using two different methods, polymerase chain reaction (PCR) and loop mediated isothermal amplification of DNA, to detect toxin genes of *C. difficile* in stool have been approved by the U.S. Food and Drug Administration (FDA). These assays have high sensitivity and specificity and possess a short turnaround time of several hours.[20] Several studies have evaluated these assays in comparison to other available diagnostic tests because of its promise as a rapid, sensitive, and specific method to diagnose CDI when applied to appropriate patient populations who meet the criteria for diarrhea (three or more loose or unformed stools in 24 hours).[22,23] One study comparing 11 different available rapid assays for diagnosis of CDI on the same 600 stool sample set found PCR testing for toxin B gene to be the most useful single test.[24] Disadvantages of these tests include cost and the risk of false-positive results in asymptomatic patients. It is important to utilize these assays only in appropriate patients to minimize both of these potential drawbacks.[20] Overall, clinical laboratories are more frequently adopting and using this type of diagnostic testing for CDI.

Treatment

The first line of treatment is to discontinue the provoking antimicrobials if they are still in use. Symptoms resolve within 48 to 72 hours in 20 to 25 percent of patients by simply stopping the offending antimicrobials.[25] Oral metronidazole and oral vancomycin for 10 days are highly effective at stopping diarrhea in patients with mild to moderately severe CDI, but metronidazole is far less expensive, and there is widespread reluctance to use oral vancomycin in hospitals because of concern about selecting vancomycin-resistant enterococci (VRE). However, randomized blinded clinical trials indicate that vancomycin is superior to metronidazole for the treatment of severe CDI and it is currently the recommended drug for treatment of severely ill patients with CDI.[26,27] Average time to resolution of diarrhea with treatment is about 3 days, but diarrhea may not resolve for 6 to 7 days.[25] Recurrences of diarrhea occur in 15 to 25 percent of patients treated with either agent.[19] For first recurrences, treatment with metronidazole should be repeated if disease is mild to moderate, but if severe, vancomycin should be given. For subsequent recurrences, there is no standardized treatment, but the use of a tapering dose of vancomycin over multiple weeks followed by pulse doses of a single dose every other to every third day has shown efficacy in uncontrolled trials.

Fidaxomicin received approval in the United States for the treatment of CDI in 2011. A randomized blinded clinical trial comparing fidaxomicin to vancomycin showed similar cure rates. There was a lower rate of recurrence seen in patients treated with fidaxomicin if the infection was due to a non-BI/NAP1/027 strain of *C. difficile.*[28]

Increasing morbidity and increasing numbers of patients with recurrent disease have accompanied the increasing rate of CDI. Patients with recurrent CDI can develop prolonged, chronic disease which can

last for years. Because of the lack of efficacy of the standard antibiotics for CDI treatment in recurrent disease, alternative therapies are being investigated. Fecal microbiota transplantation (FMT), also described in the literature as fecal transplantation and fecal bacteriotherapy, demonstrates significant potential benefit as an alternative treatment option in this context. The concept behind FMT is that recurrent CDI persists because of the altered balance of normal colonic flora in the bowel due to prior receipt of antibiotics. This provides a favorable environment for *C. difficile*to flourish. FMT addresses this problem by reestablishing the normal flora by infusion of healthy donor feces. A recent review of the literature determined a success rate of 96 percent in the approximately 200 cases of FMT reported.[29]In a recently published clinical trial designed to prospectively evaluate the benefit of FMT, patients with recurrent CDI were randomized to therapy with vancomycin alone or a brief course of vancomycin followed by duodenal infusion of healthy donor feces. The investigators stopped this trial early when an interim safety analysis revealed significantly better treatment outcomes in the study group receiving FMT.[30]Currently, timing and application of FMT has not been standardized and remains an area of controversy as discussed later in this chapter.

Early recurrences within 30 days of treatment are usually relapses with the same organism, but later recurrences are likely to be due to infection with a new *C. difficile*strain, particularly if the patient remains hospitalized. Asymptomatic persistence of *C. difficile*and its toxins in stools after treatment is relatively common and should not be looked for by repeated stool testing or be treated with additional metronidazole or vancomycin unless diarrhea recurs. The organism is most likely to disappear if the patient is left untreated. Only symptomatic patients should be treated.[19]More extensive recommendations for treatment of CDI have been published and outlined in clinical practice guidelines.[31,32]

Infection Prevention

Control measures can be divided into two general approaches: (1) interrupting horizontal transmission of *C. difficile,*and (2) minimizing the possibility of clinical illness if *C. difficile*is acquired. Many control measures have been employed, but few have shown clear evidence of effectiveness when applied in clinical situations. Recommendations for control of CDI have been reviewed by Gerding and colleagues and published in clinical practice guidelines.[32,33]Definitions for surveillance of healthcare-associated and community-associated CDI have been recommended.[34]These metrics were used as the basis for public reporting of CDI. All acute care hospitals participating in Centers for Medicare & Medicaid Services (CMS) publically report their surveillance data for CDI via the National Healthcare Safety Network (NHSN) managed by the Centers for Disease Control and Prevention (CDC). All facilities reporting to NHSN use CDC surveillance definitions and reporting instructions.[35]CMS required participating acute care hospitals to start CDI reporting in January 2013.

Measures directed at interruption of horizontal transmission include barrier precautions (hand hygiene/hand washing, gloving, isolation, and cohorting), and environmental cleaning and disinfection. Of the preceding measures, only the use of disposable gloves by personnel when handling body substances and the replacement of electronic thermometers with disposables have been shown in practice to reduce CDI rates.[36,37]It would seem to be prudent and to make sense intuitively to isolate and cohort patients and to clean the environment with sporicidal agents, but when 1:10 hypochlorite solution was used in the rooms of patients with CDI, the rate of CDI decreased significantly only on the bone marrow transplant unit, where the CDI rate was the highest. There was no effect when the

solution was used on the neurosurgical intensive care unit or general medical unit where rates were already low.[38] Given that use of hypochlorite solution is a respiratory and skin irritant, and may be caustic to environmental surfaces, it may be prudent to reserve this agent for areas of the hospital where CDI rates are high.

Major questions remain about how long patients with CDI should remain in contact isolation. It is clear that there is greater risk of HCP hand contamination in the room of a patient with symptomatic CDI than in the room of a patient who is asymptomatic. Current recommendations indicate that isolation can be stopped when diarrhea has ceased, usually for several days; however, the environment of the patient room may remain highly contaminated until it can be terminally cleaned. In outbreak situations, isolation of CDI patients has been extended for the duration of hospitalization; however, there are no controlled data to support such a measure. Widespread environmental disinfection with hypochlorite solutions has not been evaluated sufficiently for efficacy and has potential major drawbacks because of the odor, respiratory and skin irritation, and damage to surfaces. Asymptomatic carriers of *C. difficile* are difficult to identify, and may be the source of transmission to other patients; however, it is not known what should be done about them if they are detected. The best approach at this time is to recommend hand hygiene following all patient contacts. Because alcohol-based hand rubs are ineffective against *C. difficile* spores, but are highly effective against other hospital pathogens and have high usage compliance rates, they should be continued in use unless it can be shown that CDI rates are high, in which case hand washing (which is effective at spore removal) should be implemented.

Because measures to interrupt horizontal transmission of *C. difficile* have proved difficult, efforts to minimize the possibility of clinical illness if transmission occurs have been attempted. These include minimizing or preventing antimicrobial use in patients and, for patients who receive antimicrobials, various methods of prophylaxis to prevent CDI. Antimicrobial restriction of clindamycin and control of use of extended-spectrum cephalosporins have been effective at reducing CDI rates in several outbreaks.[16, 39] The prophylactic use of a yeast, *Saccharomyces boulardii*, has been shown to reduce antibiotic-associated diarrhea but not CDI in humans. Lactobacilli did not prevent antibiotic-associated diarrhea in adults, and prefeeding of live yogurt cultures does not prevent *C. difficile* diarrhea in hamsters. *C. difficile* antibodies derived from cow milk and chicken eggs prevent disease in hamsters, as does precolonization with nontoxigenic *C. difficile*, but results of studies in humans are not available. Careful risk analysis of specific antimicrobial use associated with CDI is likely to identify antimicrobials that can be controlled or restricted as part of a successful CDI prevention effort. Finally, a "bundle" approach to dealing with CDI outbreaks has also been employed with good success.[33,40]

Areas Of Controversy

The most controversial areas of CDI are those involving treatment management and diagnosis. The role of FMT in the treatment of patients with recurrent CDI is still being established. The FDA is currently developing policies for the use of FMT and emphasizes the need for informed consent that includes the caveat that this treatment modality is investigational and has potential risks.[41] The management of patients with fulminant CDI is also controversial because these patients frequently have an ileus that prevents oral treatment from reaching the colonic site of infection. The selection of the best laboratory test for detection of *C. difficile* or its toxins is also a major area of controversy. More clinical laboratories are adopting and using stool PCR testing for CDI because of its sensitivity, specificity, and rapid turnaround time. A prospective cohort study showed that using stool PCR testing instead of enzyme

immunoassay or cell cytotoxicity assay lead to a 50 percent increase in CDI incidence rate.[42]Current CDI surveillance reporting does not account for different diagnostic tests which confounds the ability to compare hospitals. This is a particular concern and area of controversy in the current era of mandatory public reporting of CDI. An additional area of controversy is whether community CDI rates are increasing and whether the number of patients with CDI who have no antimicrobial exposure is increasing.

Implications For Multiple Practice Settings

CDI rates in the ambulatory care setting are much lower than in the acute care hospital or long-term care setting, but some areas of the country are reporting increased incidence of community-associated CDI, and some of these patients have no identified antimicrobial exposure.[43]Within acute care and long-term care environments, CDI rates can be expected generally to parallel the rate of antimicrobial use in the patient population. Reports from the state of Ohio suggest that the incidence of CDI in long-term care facilities may be higher than previously observed.[44]CDI rates vary widely from institution to institution, however, and over time in a single institution.

Financial And Cost Benefits

The monetary cost of a case of CDI in a hospitalized patient in one U.S. hospital has been found to be $3,669, which projects to a national cost for U.S. hospitals of $1.1 billion each year.[45]A more recent study based on CDI experience in Massachusetts' hospitals indicates that the projected national annual hospital costs of CDI infection management are $3.2 billion.[46]Prevention of CDI has obvious financial benefit for the healthcare system, especially for the hospitalized acute care population.

Conclusions

CDI is one of the most common and costly HAIs. The risk is linked closely to the use of antimicrobials in these patients. Herein lies the problem and the opportunity for prevention. Avoidance of unnecessary antimicrobial use provides a nearly 100 percent guarantee of avoidance of CDI. Even if the best efforts to prevent transmission of *C. difficile*in the hospital are not always successful, CDI still can be prevented if the number of susceptible patients can be minimized by the practice of good antimicrobial stewardship as part of the infection prevention effort.

Future Trends

There are major needs for the following:

1. Better methods to prevent disease in hospitals and long-term care facilities, including restoration of the disrupted flora in the gut and development of vaccines.
2. Improved treatment regimens that achieve high levels of initial response and reduce the current high rate of recurrence, potentially avoiding the use of antimicrobial treatment altogether.
3. More effective therapies for patients with fulminant disease to reduce mortality and morbidity.

4. Strategy for addressing the different diagnostic assays for CDI used to improve comparisons of CDI rates among different healthcare facilities.

International Perspective

CDI occurs worldwide in hospitals and long-term care facilities and is likely to be underdiagnosed because of a lack of clinical suspicion or unavailability of laboratory testing. Rates in countries such as the United Kingdom and Australia appear to be at least as high as in U.S. hospitals, but specific comparison data are limited. The BI/NAP1/027 strain of *C. difficile*has caused outbreaks in hospitals in Canada, the United Kingdom, and Western Europe.

APIC TEXT OF INFECTION CONTROL AND EPIDEMIOLOGY

Creutzfeldt-Jakob Disease and Other Prion Diseases

Author(s): Beth Ann Kavanagh, MT(ASCP), MS, MBA, CIC
Director, Infection Control and Prevention

University Health System
San Antonio, TX

Published: October 3, 2014

Abstract

Creutzfeldt-Jakob disease is one of several neurologically degenerative diseases caused by a group of protein particles that are infectious by nature of their ability to replicate in the central nervous system and interrupt crucial neuron functioning. Creutzfeldt-Jakob disease and other prion diseases were originally called slow virus diseases because of their prolonged incubation period and initial designation as a viral condition. In the 1980s, it was proposed that the etiology of these neurodegenerative diseases was not viral in nature but due to an "infectious" protein particle that was transmissible through infected tissue and could be distinguished from any other infectious agent by a crucial lack of nucleic acid material. Creutzfeldt-Jakob disease and other prion diseases with demonstrated transmissibility remain a concern for the healthcare community because of their inherent resistance to traditional disinfection/sterilization methods and devastating clinical outcomes. Prevention measures in hospitals include Standard Precautions for general patient care and adherence to extensive chemical or increased temperature sterilization in the confines of the operating room. Prion diseases represent the frontier for infectious disease research.

Key Concepts

- Prion proteins are synthesized normally in brain tissue.
- Prion diseases occur sporadically in nature, by familial transmission (gene mutation), iatrogenically, and by ingestion of abnormal prions, as in the case of the bovine encephalopathies.
- Prions are highly resistant to routine sterilization/disinfection methods.
- Prion eradication involves chemical or increased temperature/extended cycle sterilization or a combination of both.

- Healthcare providers should be educated on prion diseases to recognize risk factors in patients and take appropriate precautions, protect the health of staff, and prevent unsuspected exposures to patients.

Background

Creutzfeldt-Jakob disease (CJD), originally known as a *slow virus*disease, was first described by Creutzfeldt in 1920 and later in 1921 by Jakob.[1]In their descriptions of the disease, the physicians noted cases of unusual neurological degeneration leading to rapid central nervous system collapse and certain death. At autopsy, the patients described were noted to have little tissue inflammation, yet they had extensive loss of normal brain tissue and replacement by glial cells, giving the brain a starlike or "spongy" (spongiform) appearance.

During the next four decades, few cases of what would come to be known as CJD were recorded in the medical literature. In 1957, CJD became associated with another slow virus disease known as *kuru*. This condition was described in the investigational work of epidemiologists studying a neurodegenerative fatal condition occurring among the Fore natives of New Guinea.[2]The distinguishing epidemiological characteristic of kuru was the practice of cannibalism among the Fore women and children. The natives freely admitted to using family members as a source of protein to feed their nutritionally depleted children while maintaining an element of ritual honoring of deceased tribal members. Cannibalism of family members dying of "shivering disease" (kuru) led directly to the transmission of this disease to women and children.

A third neurodegenerative disease, Gerstmann-Sträussler-Scheinker (GSS) syndrome, first described in 1928, was found to be similar to CJD by virtue of onset of dementia and rapid neurological degeneration leading to death.[3]Other human diseases (e.g., fatal familial insomnia) and animal encephalopathies (including scrapie in sheep and goats, transmissible mink encephalopathy, chronic wasting disease of elk and deer, exotic ungulate encephalopathy, and feline and bovine spongiform encephalopathy [BSE]) have all been grouped together into a category of neurological disorders referred to as the *transmissible neurodegenerative diseases*or *transmissible spongiform encephalopathies*(TSE). The diseases were linked by their neurological manifestations (primarily in the central nervous system), sometimes long incubation periods (as in the case of kuru and CJD), progressive and ultimately fatal outcomes, and, characteristically, the spongiform transformations in brain tissue in the absence of an inflammatory response.

In 1982, Prusiner proposed the name *prion*(proteinaceous infectious particles) for the agents that caused the transmissible neurodegenerative diseases of humans and animals. It took more than 10 years for the prion theory of disease to be accepted by the scientific community. In 1997, Prusiner won the Nobel Prize in medicine for his work on prion diseases. Prion diseases of humans are known to occur sporadically, by gene mutation (familial disease), iatrogenically, and by ingestion of contaminated meat products (e.g., beef, bone meal).

Molecular Properties Of Prions

Most research into prion diseases was done using animal models infected with the prion disease of sheep called *scrapie*. Animals with scrapie have large lesions surrounded by exfoliated areas of

sheepskin caused by rubbing or scraping of the skin on fence posts. Brain tissue studied in scrapie-infected animals contained two forms of prion protein (PrP); one form was sensitive to protease digestion, and the other form was a protease-resistant isoform designated *PrPsc*(scrapie). The normal isoform (protein configuration) of PrP, designated *PrPc,*is predominantly present on cell surfaces of uninfected animals and is rapidly synthesized and degraded in vitro. The secondary protein structure of PrPc contains only 3 percent sheeting. The abnormal form, PrPsc, in contrast, is primarily found in infected vesicles, contains 43 percent sheeting in its secondary protein structure and is slowly synthesized and degraded in vitro.[4]The secondary protein structure is important in understanding mechanisms to inactivate or denature the protein.

Purification of PrPsc from the brains of scrapie-infected animals allowed the amino acid sequence of the protein to be determined and subsequently the mapping of the *PrP*gene.[5]The *PrP*gene has been located on the short arm of human chromosome 20 and a homologous region of the mouse chromosome 2.[6]

The *PrP*gene is closely linked to genes that control the incubation time to onset of disease in scrapie-infected mice and confirms that PrP plays a crucial role in prion disease development.

PrPsc accumulates in the cells primarily in cytoplasmic vacuoles and lysosomes. It arises from a posttranslational conversion of normal PrPc to the abnormal isoform after an infectious dose of PrPsc has been introduced into the brain.[7]Studies indicate that when PrPsc is introduced into the brain, it disseminates by slowly spreading within the axons of nerve cells and accumulating within cells.[8]PrPc and PrPsc molecules bind together to convert the normal PrPc to the abnormal PrPsc isoform. When introduced into the brain, PrPsc replicates; many models of prion replication have been put forward.[9]As PrPsc interacts with PrPc and causes an unfolding and refolding of the protein conformation, an exponential conversion of PrPc to PrPsc occurs. The cascade of accumulations of the replicated abnormal PrPsc results in neuronal dysfunction by a process not yet clearly defined.

Mutations in the *PrP*gene are responsible for inherited human prion diseases, including familial CJD, GSS syndrome, and fatal familial insomnia.[10]More than 20 different mutations have been identified, including a common mutation on a lysine-for-glutamic acid substitution in codon 200. Recently, it was discovered that a polymorphism of methionine/valine on codon 129 created distinctive histopathological lesion profiles that determined the clinical course of those affected with variant forms of CJD (vCJD).[11]

Characteristics Of Creutzfeldt-Jakob Disease

CJD occurs naturally in either of two forms: the sporadic type (occurring at a rate of 1 case per 1 million population) and the familial type due to a genetic mutation that can be passed from generation to generation and has been documented in geographical clusters in various parts of the world.[12]Most recorded cases are of the sporadic type (85 to 95 percent), but the bulk of available knowledge of the pathogenesis of CJD and the role of the *PrP*gene has come from studies done on the familial cases. Iatrogenic CJD also has occurred, caused by introduction of prion-laden tissue (transplanted or extracted from diseased individuals) into the brain or body of an otherwise healthy patient or by the use of contaminated medical (neurosurgical) equipment during an invasive procedure or surgery. This condition has occurred when tissue transplants (dura mater, pericardium, and cornea) have been taken from patients with unsuspected CJD at the time of death and used as donor organs/tissue in transplantation procedures. Pooled pituitary hormone preparations (growth hormone and gonadotropin)

harvested from cadavers have also contributed to many iatrogenic CJD cases.[13]Contaminated surgical equipment or implantation of electrodes deep in the brain can also transmit infectious prions from one patient to another.

Sporadic CJD has no gender restrictions and occurs at a mean onset of 50 to 70 years of age. Earlier onset of symptoms is more characteristic of new, variant forms of CJD (vCJD), which have been associated with consuming contaminated meat products or iatrogenic sources of infection in which large inoculum size may influence onset of symptoms. The classic disease occurs as a rapid and progressive dementia with several distinctive clinical manifestations, including ataxia, myoclonic seizures, visual or sensory deficits, abnormal psychiatric behavior, and coordination deficits. Mental deterioration of the patient occurs rapidly. The average time frame from onset of symptoms to time of death is 7 to 9 months. Patients with CJD may show abnormalities on electroencephalogram. A characteristic pattern consisting of a slow background of waves with generalized bilateral synchronized biphasic or triphasic periodic sharp wave complexes is present in 67 to 95 percent of patients.[14]

Definitive diagnosis of CJD is made by direct examination of the brain tissue. The observation of neuronal loss, reactive gliosis, and neuronal vacuolation (spongiform appearance) with an absence of inflammatory cells is consistent with the diagnosis of CJD.[15]Routine diagnostic tests are rarely of value in making a diagnosis of CJD. Cerebrospinal fluid (CSF) from patients with suspected CJD is usually found to be acellular with normal glucose levels and protein that may be slightly elevated. Some patients have been found to have elevated serum protein levels of S100 protein.[16]Proteins that are found specifically in the CSF may be more useful in diagnosing CJD, however. One such specific protein is called the *14–3-3 protein*, for which Western blot assays have been developed. The 14–3-3 protein has been reported in 95 percent of patients with sporadic CJD and less frequently with familial CJD.[17]

Elevations of this protein also can be seen in patients with herpes encephalitis, metabolic encephalopathy, intracerebral metastatic cancer, and hypoxic encephalopathy, resulting in some degree of false positivity when the test is used. Computed tomography (CT) scans and magnetic resonance imaging (MRI) also have been used to detect abnormalities in patients with rapidly progressive dementia, but the exact sensitivity and specificity of these tests have not been well established for CJD. A CT scan shows cerebral atrophy in CJD as opposed to cerebellar atrophy. MRI utilizing diffusion weight (DWI) and fluid attenuated inversion recovery (FLAIR) images have been shown to have a sensitivity of >90 percent in detecting characteristic changes in the basal ganglia thalamus and cortex. Radiologists who are not familiar with changes noted in CJD may miss subtle changes that are primarily seen within the cortex or perceive lesions as artifact.[18]Immunological tests (monoclonal and polyclonal antibodies) for PrPsc have proved to be sensitive and specific in brain tissue that is obtained at autopsy or by brain biopsy.[19]

In 1997, the National Prion Disease Pathology Surveillance Center was established at Case Western Reserve University to provide a variety of diagnostic tests to aid in the confirmation of CJD and to perform surveillance activity for prion disease in the United States. The center performs Western blot assays on brain tissue, immunohistochemical tests for PrP on fixed tissue, analysis of DNA extracted from blood or brain, and analysis of CSF for 14–3-3 protein.

Other Prion Diseases

GERSTMANN-STR&AUML;USSLER-SCHEINKER SYNDROME

GSS syndrome is a genetically transmitted prion disease due to an autosomal dominant type of inheritance. The disease occurs at a rate of 1 to 10 cases per 100 million population per year, making it an extremely rare disease. The mean onset of the disease is 43 to 48 years with an average of 5 years' duration of clinical illness. The most striking feature of the disease is progressive spinocerebellar degeneration and accompanying dementia.[20]Impairment of the individual affects intelligence, memory, attention, and cognitive thinking skills. Clinical findings include ataxia, tremors, spasticity, nystagmus, and dysarthria. Laboratory tests for GSS syndrome generally are not helpful. Definitive diagnosis of the disease requires visual examination of the brain tissue and findings of amyloid plaques detected primarily in the cerebellum.

FATAL FAMILIAL INSOMNIA

Fatal familial insomnia (FFI) is one of the newer prion entities to be described. This disease also is transmitted genetically through autosomal dominance. The characteristic feature of the disease is the presentation of insomnia with dysautonomia, tachycardia, hypertension, and motor deficits and changes that include spasticity, hyperreflexia, and dysarthria. Patients can have hallucinations, memory problems, and confusion.[15]The mean onset of the disease is in middle age (35 to 61 years old) with duration of the course of disease approximately 13 months until death.

NEW VARIANT CREUTZFELDT-JAKOB DISEASE

In 1995, it was recognized that patients significantly younger than 50 years of age were diagnosed with symptoms similar to CJD. Thirty-nine cases of vCJD were described in British medical journals in 1997 and 1998.[21,22]The patients had a mean age of onset of 29 years (range, 16 to 48 years), and the duration of illness was approximately 14 months (longer than sporadic CJD). In contrast with classic CJD cases, these patients had sensory and psychiatric deficits and disturbances. Their symptoms included pain, dysesthesias, and paresthesias of the face, hands, feet, and legs. Psychiatric manifestations included depression, psychosis, and anxiety and resultant weight loss, withdrawal, apathy, and personality change. Auditory hallucinations were noted in several cases. Definitive diagnosis of vCJD can be made only from direct examination of the brain tissue. Patients with CJD may have PrPsc detectable in lymphoid tissue. The pathological characteristics of the disease are different from sporadic or classic CJD. The vCJD cases sampled at autopsy showed spongiform changes and amyloid plaques distributed throughout the cerebellum. The plaques had dense eosinophilic centers and pale peripheries upon being stained for PrPsc.[21]

When subjected to electrophoresis, PrPsc from vCJD cases has mobility patterns distinct from sporadic CJD and more similar to the PrPsc from BSE cases.[23]It has been proposed that vCJD is the result of bovine-to-human transmission of BSE. This suggestion is based on the observation that cases of vCJD were described after large outbreaks of BSE in the United Kingdom when infected cattle may have been introduced into the marketplace. It is speculative how many individuals will develop vCJD in the United Kingdom and in other countries where epidemics of BSE have occurred. The incidence of CJD cases in the United Kingdom increased from 3 in 1995 to 28 in 2000 with many deaths.[24]

In 2002, the first case of vCJD was reported in the United States by the Florida State Health Department.[25]The patient had lived in the United Kingdom from 1980 to 1992 and was likely exposed to BSE during that time. Since that time, two additional cases have been reported in the United States;

one patient was born and raised in the United Kingdom, and the other case had been exposed to BSE-contaminated cattle products in Saudi Arabia. Since 1996 (current to June 28, 2012), 227 vCJD cases have been reported within 12 countries. Of the 227 cases, 182 cases had resided in either the United Kingdom or alternatively in France (27 cases). Information on the vCJD cases can be found at **http://www.cdc.gov/ncidod/dvrd/vcjd/factsheet_nvcjd.htm**.

BLOOD AND ORGAN DONATION

As global travel expands, it is increasingly likely that European citizens with BSE will seek medical treatment in the United States. Travel history and time spent living in countries where BSE has been diagnosed have become part of screening tools used to determine if a patient is considered a high-risk candidate for surgery or blood and organ donation. Persons who resided in or traveled to the United Kingdom for 6 months or more between 1980 and 1996 are not permitted to donate blood or plasma in the United States.[26]Information about blood eligibility in the United States is found on the website of the

American Red Cross: Giving Blood: Blood Eligibility Guidelines (**http://www.redcrossblood.org/donating-blood/eligibility-requirements/eligibility-criteria-alphabetical-listing#arc3**).

Transmission Of Prion Diseases

Prion diseases are not spread person to person, and in general patients with prion diseases can be cared for by healthcare personnel and family members without risk of transmission of infectious particles. Iatrogenic cases of prion disease have occurred as the result of direct inoculation of prion particles into the brain or spinal cord of patients undergoing procedures in the hospital. Contaminated surgical equipment or electrodes in the brain also have transmitted infectious prions from one patient to another. In these instances, standard sterilization/disinfection methods have been inadequate.

It is very important that patients who are known or suspected to have prion disease are identified before any surgical procedure involving tissues that may be infectious. Instruments used in these cases will require special processing; environmental cleaning and disinfecting in surgery and laboratory settings will require procedures that will inactivate prions; and disposal of contaminated waste will require special handling. Specifics can be found in the CJD in Patient-Care Areas section of the Healthcare Infection Control Practices Advisory Committee's 2003 guidelines for environmental infection control in health-care facilities[27](**http://www.cdc.gov/mmwr/preview/mmwrhtml/rr5210a1.htm**).

Outside of the hospital, prion transmission can occur by an oral route or by ingestion of infectious particles. This route of transmission is not an efficient one but may be effective if repeated doses of prion particles are introduced through multiple feedings. Ingestion is the characteristic route of transmission for kuru, and the implied route for vCJD, and is most likely responsible for other spongiform encephalopathies common among animal species. Transmission of prion particles in animals may be limited by a species barrier that depends on the homology of the prions and the ability of the PrPsc to interact with the PrPc.[24]Humans seem to be susceptible to animal encephalopathies, however,

as in the case of hunters ingesting infected organs and meat from wild animals (squirrels or elk) during hunting season and developing disease.[28]

In the healthcare setting, risk of transmission to patients has been associated with direct contact with infectious tissues. A hierarchy of infectivity of various tissues in the healthcare setting has been

suggested by Rutala.[28] Table 73-1 provides a comparison of the World Health Organization (WHO) infectivity categories to those suggested by Rutala and Weber.[29]

Tissues known to be highly infectious include brain, dura mater, pituitary tissue, spinal cord, and eye; tissues of low infectivity include lung, liver, kidney, spleen, lymph nodes, and CSF. No known risk of transmission is associated with contact with blood. No known infectivity has been detected in heart, skeletal muscle, peripheral nerves, adipose tissue, gingival tissue, intestine, adrenal gland, thyroid, prostate, or testes, or in bodily secretions or excretions such as sweat, tears, saliva, phlegm (sputum), stool, urine, semen, and breast milk. Risk assessment and prevention of exposure through the use of personal protective equipment and disposable equipment are the best means to reduce any risk of transmission in the healthcare setting.

Table 73-1 Transmissible Spongiform Encephalopathy and Tissue Infectivity: A Comparison of World Health Organization Infectivity Categories* to Rutala and Weber Recommendations**

WHO Categories†	Rutala and Weber Categories‡	WHO Tissues, Secretions, Excretions by Infectivity Category	Rutala and Weber Tissues, Organs, Body Fluids by Risk Category
High infectivity	High risk—from a high-risk patient§	Brain, spinal cord, retina, optic nerve, spinal ganglia, trigeminal ganglia, pituitary gland, dura mater	Posterior eye, brain (including dura mater), spinal cord, pituitary tissue
Low infectivity	Low risk—from high-risk patient	Peripheral nerves, spleen, lymph node, tonsil, rectum, placenta, ovary, uterus, lung, liver, kidney, cornea, blood, CSF	CSF, kidney, liver, lung, lymph nodes, spleen, placenta, olfactory epithelium

Available at: **http://www.who.int/bloodproducts/cs/TSEPUBLISHEDREPORT.pdf**. Paragraph 4, page 117: "It is also important to understand that categories of infectivity are not the same as categories of risk, which require consideration not only of the level of infectivity in tissue, but also of the amount of tissue to which a person or animal is exposed, and the route by which infection is transmitted. For example, although the level of tissue infectivity (concentration of infectivity in tissue as reflected by titre) is the most important factor in estimating the risk of transmission by instrument cross-contamination during surgical procedures (e.g., neurosurgery versus general surgery), it is only one determinant of the risk of transmission by blood transfusions, in which a large amount of low-infectivity material is administered directly into the circulation, or the risk of transmission by food that, irrespective of high or low infectivity, involves the comparatively inefficient oral route of infection."

Comparative frequency of infectivity in organs, tissue and body fluids of humans with transmissible spongiform encephalopathies (Creutzfeldt-Jakob Disease). "Footnote a: high risk indicates a rate of transmission to inoculated animals of ≥50%; low risk indicates a rate of transmission to inoculated animals ≥10%–20% (except for lung tissue, for which transmission is 50%); no risk indicates a rate of transmission to inoculated animals of 0% (several tissues in this category had few tested specimens)."
§Rutala WA, Weber DJ. Creutzfeldt-Jakob disease: recommendations for disinfection and sterilization. *Clin Infect Dis*2001;32:1352. "High risk patient-patient with suspected or known CJD."

Iatrogenic transmission within the healthcare setting can occur when patients are exposed directly to infectious prion materials via inadequately sterilized neurosurgical equipment, contaminated lyophilized dura mater, corneal transplants, cortical electroencephalogram electrodes, and injections of cadaveric pituitary-derived growth hormone.[24] A 2003 Centers for Disease Control and Prevention (CDC) report summarized 97 cases of iatrogenic transmission of CJD in Japan related to receipt of dura mater grafts from cadavers. The vehicle of transmission was a single brand of dural graft (Lyodura; B. Braun Melsungen AG, Melsungen, Germany) produced in Germany before May 1987.[30] A recent update of the related cases of CJD identified through surveillance by the Japanese Ministry of Health and Welfare that were associated with use of this graft material has brought the total number of cases to 132.[31] All the patients had received dura mater grafts between 1978 and 1993 for tumors, brain hemorrhage, trigeminal neuralgia treatment, intracranial aneurysm, hematoma from trauma, unspecified anomalies, and ossification of the spinal posterior longitudinal ligament. Illness onset occurred from 1985 to 2006, with the incubation period ranging from 1.2 to 24.8 years with a median and mean incubation of 12.4 and 11.8 years, respectfully. The first case of CJD associated with a Lyodura graft was reported in the

United States, and the company actively worked with authorities to revise collection and processing of the graft material to reduce the risk of prion transmission.

No known transmission of sporadic CJD by blood has been documented. However, since December 2003, four transfusion-related cases of vCJD have been described.[32,33] In some countries affected by BSE outbreaks, blood products are leukodepleted because of the potential transmissibility of vCJD through lymphoreticular tissues.[34] The risk of acquiring CJD after any surgery has also been studied, and the risk for acquisition of sporadic CJD is actually noted to be slightly higher after general surgical procedures than neurological surgery.[35]

Healthcare personnel are hypothetically at risk for work-related exposures when they may have been exposed to high-risk tissues. There are reported incidences of a pathologist, two neurosurgeons, an orthopedic research physician, nurses, and histology technicians who have been diagnosed with CJD, but these have occurred at the same incidence as in the general population.[36,37] Among healthcare personnel, an incidence of disease of 1 to 1.8 per 1 million healthcare personnel is considered to be expected. Even a hypothetical risk necessitates that an awareness of potential for transmission and use of precautions and barriers is appropriate. Standard Precautions should be used when handling items contaminated with high-risk tissues from patients with confirmed or suspected disease, and those items should be labeled "biohazardous" or "Prion Precautions." Attention should be focused on avoiding needlestick exposures, splashes into mucous membranes, and scalpel injuries when high-risk tissues are being handled or encountered. Disposable equipment should be used for invasive procedures, such as lumbar punctures and CSF specimen collection, whenever possible.[38]

Because bovine and other animal products may be involved in the manufacture of biological and pharmaceutical products, such as animal feeds, vaccines, and bacterial and eukaryotic cell lines, care must be taken in the removal, processing, and handling of all tissues that could potentially be contaminated with spongiform encephalopathies, primarily vCJD, that could be transmitted to humans.[32]

Methods For Inactivation Of The Creutzfeldt-Jakob Disease Agent

Prion diseases such as CJD represent a unique infection prevention problem because prions exhibit an unusual resistance to conventional chemical and physical decontamination methods. Because CJD is not readily inactivated by conventional disinfection and sterilization procedures, and because of the invariably fatal outcome of CJD, the procedures for disinfection and sterilization of the CJD prion have been conservative and controversial. Recommendations to prevent transmission of infectious prions from contaminated medical devices have been based primarily on prion inactivation studies.

DISINFECTION AND STERILIZATION

Recommendations for the cleaning and sterilization of instruments used on patients with suspected or confirmed CJD have been provided by the WHO.[38] The recommendations from the WHO are based on exposure to highly infectious material (brain, spinal cord, and eyes) versus low-infectivity tissues (CSF, kidneys, liver, lungs, lymph nodes, spleen, and placenta). The final recommendations on sterilization and disinfection came from studies that intentionally contaminated equipment with brain tissue or tissue homogenates from patients with CJD and tested tissue for prion log decrease. In contrast with routine

hospital protocol, no precleaning procedures (enzymatic or detergent/decontamination treatment) were done. Precleaning normally reduces microbial contamination by 4 logs.[28]The major intent of sterilization is the further log reduction of prion particles to a negligible number because prions are resistant to conventional sterilization processes. Variables in the disinfection studies done included the prion strain, prion concentration, test tissue, test animal, duration of follow-up, method of calculating the log decrease of the prion with disinfection, and exposure conditions. All studies have shown, however, that the TSE agents are difficult to inactivate.[39]No studies reflect reprocessing procedures in a clinical setting.

Another component that must be integrated into the disinfection and sterilization process is the risk of infection associated with the use of the medical device. Medical devices are categorized as *critical, semicritical,*or *noncritical*. All critical and semicritical instruments/equipment can be exposed to potentially infectious material (high-risk and low-risk tissue). Critical items are items that enter sterile tissue or the vascular system and include surgical instruments and implants. Semicritical items have contact with mucous membranes or nonintact skin (e.g., endoscopes and respiratory therapy equipment). Noncritical items (e.g., floors, walls, blood pressure cuffs, and furniture) come in contact with intact skin but not with mucous membranes. Intact skin should act as an effective barrier to microorganisms and prions.

Conventional sterilization methods are not acceptable for critical and semicritical items that have contact with high-risk tissue (e.g., brain) from a high-risk patient (e.g., with suspected or known CJD), and they must be reprocessed in a manner to ensure the elimination of prions or be disposable. The combined contribution of cleaning and use of an effective physical or chemical reprocessing procedure should eliminate the risk of CJD transmission. Critical or semicritical instruments or medical devices that have contact with low-risk or no-risk tissue can be treated by means of conventional methods because the devices have not resulted in transmission of CJD.

EFFECTIVENESS OF DISINFECTION OR STERILIZATION PROCEDURES

The reduction of infectious units, defined in the literature as the $\log_{10}$lethal dose $(LD)_{50}$/g of infectious material, occurring during the disinfection or sterilization process is referred to as the *inactivation*or *removal factor*.[40,41,42]The probability of an instrument remaining capable of transmitting disease depends on the initial degree of contamination and the effectiveness of decontamination procedures. An instrument contaminated with 50 mg of brain tissue from a person infected with CJD and with a titer of 1×10^5(50 percent LD intracerebral units/g) would have 5×10^3infectious units of prion.[43]It has been suggested that a titer loss of 10^4prions should be regarded as an indication of appropriate disinfection of CJD.[42]The effectiveness of a disinfection or sterilization procedure should be considered, however, in conjunction with the effectiveness of cleaning. Studies done with microbial agents show that cleaning according to the conventional methods used in current healthcare practice results in a reduction of 10^4infectious units. Cleaning followed by disinfection would result in a reduction of 10^7infectious units (4-log reduction with cleaning plus a >3-log reduction due to effective sterilization). If tissues with high prion infectivity (e.g., brain) are contaminated with 10^5prions/g, cleaning followed by use of a sterilization procedure should eliminate infectivity and provide a significant margin of safety.

DISINFECTION

Prions exhibit an unusual resistance to conventional chemical and physical decontamination methods. Most disinfectants are inadequate for the elimination of prion infectivity. Antimicrobial agents that have been shown to be ineffective (<3 log reduction in 1 hour) against CJD or other TSEs are listed in Table

73-2.[40,41,42,44,45,46,47,48,49] A formic acid soaking is required for inactivation of prion infectivity in tissue specimens obtained from patients with CJD.[50] Formic acid causes the prion proteins to unfold and inactivate.

Table 73-2 Ineffective or Unreliable Methods of Eliminating Infectivity

Acetone
Ethanol
Glutaraldehyde
Ortho-phthalaldehyde
Peroxidate
Ammonia
Hydrochloric acid
Phenolics
Chlorine dioxide
Ethylene oxide
Hydrogen peroxide
Potassium permanganate
Detergents (unless specific formulation)
Formaldehyde
Iodophor
Radiation dry heat
Freezing
Peracetic acid
Routine steam sterilization
Microwave
UV light
Tego (dodecyl-di[aminoethyl]-glycine)
Sodium deoxycholate
Sodium dodecyl sulfate

There are four chemicals that reduce the titer of infectious units by greater than 4 logs: chlorine, phenol, guanidine thiocyanate, and sodium hydroxide.[40,41,42,44,45,51,52,53,54] Of these chemical compounds, the disinfectant that is readily available and that provides the most consistent prion inactivation results is chlorine.[44] The corrosive nature of chlorine makes it unsuitable, however, for

semicritical devices, such as endoscopes. Flexible and rigid endoscopes have been used in brain surgery.[55,56] If these endoscopes come into contact with high-risk tissue in a patient with known or suspected CJD, either the scopes should undergo sterilization (if possible) or single-use devices should be used. Endoscopes that come into contact with other tissues (e.g., from the gastrointestinal tract, respiratory tract, joints, and abdomen) can be disinfected by conventional methods. Table 73-3 provides a comparison of recommendations for disinfection and sterilization of instruments/equipment used for patients with suspected/known TSE noting the WHO guidelines and those outlined by Rutala and Weber. This table provides its own citations for convenience of the reader in evaluating the comparisons.

Table 73-3 WHO Infection Control Guidelines for Transmissible Spongiform Encephalopathies versus Rutala and Weber Creutzfeldt-Jakob Disease: Recommendations for Disinfection and Sterilization

Patient Category	Tissue Risk Category	Medical Device Category[1]	Options for Instrument Disinfection/Sterilization	
Confirmed orSuspected Cases of TSE	**High Risk/Infectivity** NB.**WHO states:**"Although CSF is classified as a low infectivity tissue and is less infectious than high infectivity tissues instruments contaminated by CSF should be handled in the same manner as those contacting high infectivity tissues."[2]	**Critical & Semicritical**	**WHO Heat-resistant Instrument Options[3]**	**Rutala/Weber He Instrument Recor**
Incineration is the preferred method for all instruments exposed to high infectivity tissues.	No recommendation for incineration of reusable instruments. Instruments that cannot be cleaned may be discarded or subjected to alternate methods of decontamination/sterilization.	**No**		
Surgical instruments that are going to be reused may be mechanically cleaned in advance of subjecting to decontamination/sterilization. Instruments should be kept moist to prevent tissue adherence. Instruments to be cleaned in automated mechanical processors must be decontaminated before processing through these machines and the washers (or other equipment) should be run through an empty cycle before any further routine use.	Mechanically clean devices that are constructed so that cleaning procedures result in effective tissue removal. Instruments should be kept moist until cleaned and decontaminated. Cleaning of instruments in a washer-disinfector is acceptable. Decontamination should occur as soon as possible. After the device is clean, it should be sterilized by either autoclaving (i.e. steam sterilization) or using a combination of sodium hydroxide and autoclaving.	**Partial**		

	Rutala/Weber Considers CSF as low risk and originally did not recommend handling instruments contaminated with CSF in the same manner that instruments contaminated with high-risk tissues were handled. Now more consistent with WHO and other entities.		WHO Option # 6 (see below) agrees with Rutala/Weber Option # 1 with regard to cleaning instruments and sterilizing by autoclaving at 134°C for ≥18 min in a prevacuum sterilizer; no mention is made of cleaning alone followed by gravity displacement sterilizer at 121° to 132°C.	**Rutala/Weber Op** that are construc cleaning procedu effective tissue re surgical instrume cleaned and then autoclaving at 13 min in a prevacu at 121° to 1 hour in a gravity sterilizer.
WHO Option # 1: Immerse in sodium hydroxide (1 *N*NAOH which is 40 g of NAOH in 1 liter of water) and heat in a gravity displacement autoclave at 121°C for 30 min; clean, rinse in water, and subject to routine sterilization.	No recommendation for immersing in NAOH and simultaneously heating in a gravity displacement autoclave.	**No**		
WHO Option # 2: Immerse in sodium hydroxide (1N NAOH) or sodium hypochlorite (20,000 ppm available chlorine; common commercial formulation of bleach is 5.25 percent sodium hypochlorite to attain 20,000 ppm and 1 part bleach plus 1.5 parts water should be used) for 1 hour; transfer instruments to water; heat in a gravity displacement autoclave at 121°C for 1 hour; clean and subject to routine sterilization.	No recommendation for first immersing in 1N NAOH or sodium hypochlorite (20,000 ppm) followed by higher sterilization temperatures for extended times. No recommendations for the use of sodium hypochlorite.	**No**		
WHO Option # 3: Immerse in 1N NAOH or sodium hypochlorite (20,000 ppm) for 1 hour; remove and rinse in water; then transfer to open pan and heat in a gravity displacement autoclave at 121°C or a porous load (prevacuum) autoclave at 134°C for 1 hour; clean and subject to routine sterilization.	No recommendation for first immersing in 1N NAOH or sodium hypochlorite (20,000 ppm) followed by higher sterilization temperatures for extended times. No recommendations for the use of sodium hypochlorite. No recommendation for prevacuum autoclave for 1 hour, recommended time is ≥18 min.	**No**		
WHO Option # 4: Immerse in 1N NAOH and boil for 10 min at atmospheric pressure; clean, rinse in water, and subject to routine sterilization.	No recommendation for immersing in 1N NAOH and boiling.	**No**		

			WHO Option # 5: Immerse in sodium hypochlorite (20,000 ppm available chlorine) (preferred) or 1N NAOH (alternative) at ambient temperature for 1 hour; clean; rinse in water, and subject to routine sterilization. Alternative of immersion in 1N NAOH for 1 hour followed by routine sterilization is congruent with Rutala/Weber Option # 2.	**Rutala/Weber Op** that are impossib clean should be c No recommendat immersion in sod hypochlorite.
WHO Option # 6: Autoclave at 134°C for 18 min (in worse case scenarios; e.g., brain tissue bake-dried onto surfaces) infectivity will be largely but not completely removed.[5]	Only those instruments that are constructed so that cleaning procedures result in effective tissue removal are recommended for cleaning followed by prevacuum autoclaving at 134°C for >18 min. Instruments that are impossible or difficult to clean should be discarded.	**No**		
Confirmed or Suspected Cases of TSE	**High Risk/Infectivity** Eye, brain, spinal cord NB: WHO includes CSF, Rutala/Weber do not include CSF	**Critical & Semicritical**	**WHO Heat Sensitive Instruments Options**[6]	**Rutala/Weber He** **Instrument Recor**

	WHO Recommendation: Complex and expensive instruments that cannot be subjected to the recommendations for heat-resistant instruments should, to the extent possible, be protected from surface contamination. Those parts of the instrument that come into contact with internal tissues of patients should be subjected to the most effective decontaminating procedure that can be tolerated by the instrument. All adherent material must be removed and, if possible, the exposed surfaces cleaned using a decontamination method recommended in Annex III of the WHO recommendations. WHO recommendations in Annex III entitled, Chemical methods for surfaces and heat sensitive instruments state: flood with 2N NAOH or undiluted sodium hypochlorite; let stand for 1 hour; mop up and rinse with water. Where surfaces cannot tolerate NAOH or hypochlorite, thorough cleaning will remove most infectivity by dilution and some additional benefit may be derived from the use of one or another of the partially effective methods listed in Section 5.1. (Section 5.1 refers the reader to options 1–6 listed above.) No mention is made of utilization of low temperature sterilization methods (e.g., ethylene oxide or hydrogen peroxide gas plasma) after disinfection to sterilize critical or semicritical instruments.[8]	Items that permi temperature steri ethylene oxide or peroxide gas plas discarded.

Confirmed or Suspected Cases of TSE	**High Risk/Infectivity**Eye, brain, spinal cord NB: WHO includes CSF for decontamination purposes, Rutala/Weber do not include CSF AND **Low Risk/Infectivity** **WHO:**Kidney, liver, lung, lymph nodes, placenta, spleen **Rutala/Weber:**CSF, kidney, liver, lung, lymph nodes, spleen	**Critical & Semicritical**	**WHO Recommendation Instruments Reused Prior to Appropriate Decontamination/Sterilization**	**Rutala/Weber Re Instruments Reus Appropriate Decontamination**
"Decontamination and sterilization recommendations should be applied even if the instrument has been re-used before discovery of potential contamination"[9] Note: WHO does not distinguish whether this recommendation applies to only those instruments that came in contact with high-risk/infectivity tissue or low-risk tissue.	"Contaminated items that are not processed according to these recommendations (e.g., medical devices used for brain biopsy before diagnosis) should be recalled and appropriately reprocessed. Hospitals should consider using the aforementioned guidelines for neurosurgical instruments (heat resistant and heat sensitive) on patients undergoing brain biopsy when a specific lesion has not been demonstrated. Alternatively, neurosurgical instruments used in such cases could be disposable."[10] Note: This recommendation appears only in the recommendation section for critical and semicritical items used on high-risk tissue from patients with confirmed or suspected of CJD.	**Partial**		
Confirmed or Suspected Cases of TSE	**Low Risk/Infectivity** **WHO:**Kidney, liver, lung, lymph nodes, placenta,spleen **Rutala/Weber:**CSF, kidney, liver, lung, lymph nodes, spleen	**Critical & Semicritical**	Options 1–6 listed above (found in WHO Infection Control Guidelines for Transmissible Spongiform Encephalopathies, Annex III) apply.[11]	These instrument cleaned and eith sterilized by use protocols of heat sterilization or hi disinfection.[12]

Confirmed or Suspected Cases of TSE	**No Risk/Infectivity** See Table 1 for WHO and Rutala/Weber listing of No Risk/Infectivity tissues and body fluids	**Critical & Semicritical**	Routine cleaning and disinfection procedures.[13]	These devices/ins cleaned and eith sterilized by mea conventional prot chemical steriliza means of high-le Endoscopes (exce endoscopes) wou contaminated onl materials, and th cleaning and high disinfection protc adequate reproce
Confirmed or Suspected Cases of CJD	**All tissue categories**	**Critical & Semicritical**	Options 1–6 listed above (found in WHO Infection Control Guidelines for Transmissible Spongiform Encephalopathies, Annex III) apply.[15]	No distinction is vCJD and other T to cleaning/disinfect recommendations
Persons with known prior exposure to human pituitary derived hormones, cornea, or dura mater grafts	**High Risk/Infectivity** Eye, brain, spinal cord; WHO includes CSF **Low Risk/Infectivity WHO:**Kidney, liver, lung, lymph nodes, placenta, spleen **No Risk/Infectivity**	**Critical & Semicritical**	**WHO Recommendations for High Risk/Infectivity:**Options 1–6 listed above (found in WHO Infection Control Guidelines for Transmissible Spongiform Encephalopathies, Annex III) apply.[16] **WHO Recommendations for Low Risk/Infectivity:**routine cleaning and disinfection procedures.[17] **WHO Recommendations for No Risk/Infectivity:**routine cleaning and disinfection procedures.[18]	Address persons or confirmed TSE address persons exposure to hum derived hormone dura mater grafts suspected or con TSE.
Members of families with heritable forms of TSE	**High Risk/Infectivity**Eye, brain, spinal cord WHO includes CSF **Low Risk/Infectivity WHO:** Kidney, liver, lung, lymph nodes, placenta, spleen **No Risk/Infectivity**	**Critical & Semicritical**	**WHO Recommendations for High Risk/Infectivity:** No consensus reached. The majority felt that the TSE decontamination Options 1–6 listed above (found in WHO Infection Control Guidelines for Transmissible Spongiform Encephalopathies, Annex III) should be used but a minority of WHO guidelines' authors felt this was unwarranted.[19] **WHO Recommendations for Low Risk/Infectivity:**routine cleaning and disinfection procedures.[20]	Address persons or confirmed TSE address family m heritable forms o not suspected or have TSE.
			WHO Recommendations for No Risk/Infectivity: routine cleaning and disinfection procedures.[21]	

Confirmed or Suspected Cases of TSE	**High Risk/Infectivity**Eye, brain, spinal cord WHO includes CSF	**Noncritical equipment**	**WHO Recommendations:**It is important to mechanically clean and disinfect equipment and surfaces that are subject to potential contamination. Surfaces that are contaminated by TSE agents can be disinfected by flooding for 1 hour, with NAOH or sodium hypochlorite, followed by water rinses (see Annex III). WHO recommendations in Annex III entitled, Chemical methods for surfaces and heat sensitive instruments state: "flood with 2N NAOH or undiluted sodium hypochlorite; let stand for 1 hour; mop up and rinse with water."[22] Note change in concentration of these agents.	Noncritical equip contaminated wit tissue (from conf case of TSE) shou then disinfected dilution of sodiur or 1N NAOH dep material compatil contaminated sur exposed to the d Immersion time i recommendations however, studies Rutala/Weber Re Table 3 (p. 1351) immersion in sod (studies list varia available chlorine 000–10,000 ppm) reduction of prio
Confirmed or Suspected Cases of TSE	**High Risk/Infectivity**Eye, brain, spinal cord WHO includes CSF	**Noncritical environmental surfaces**	**WHO Recommendations:**It is important to mechanically clean and disinfect equipment and surfaces that are subject to potential contamination. Surfaces that are contaminated by TSE agents can be disinfected by flooding for 1 hour, with NAOH or sodium hypochlorite, followed by water rinses (see Annex III). WHO recommendations in Annex III entitled, Chemical methods for surfaces and heat-sensitive instruments state: "flood with 2N NAOH or undiluted sodium hypochlorite; let stand for 1 hour; mop up and rinse with water." Note change in concentration of these agents.	"Environmental s (noncritical) cont high-risk tissues (surface in contac tissue of a perso CJD) should be cl spot-decontamina dilution of sodiur (i.e., bleach) for of at least 15 mi

Confirmed or Suspected Cases of TSE	**Low Risk/Infectivity** **WHO:**Kidney, liver, lung, lymph nodes, placenta, spleen **Rutala/Weber:**CSF, kidney, liver, lung, lymph nodes, spleen	**Noncritical environmental surfaces**	**WHO Recommendations:**It is important to mechanically clean and disinfect equipment and surfaces that are subject to potential contamination. STERILIZATION

Although there is some disagreement about the ideal time and temperature cycle,[57]the recommendations of 121°C to 132°C for 60 minutes (gravity) and of 134°C for 18 minutes or more (prevacuum) are reasonable on the basis of the scientific literature. These methods should result in a decrease of greater than 5 logs, and adequate cleaning should result in an additional 4-log

reduction, which provides a significant margin of safety (brain tissue concentration 10^5prions/g).[43]Other steam sterilization cycles, such as 132°C for 15 minutes (gravity), have been shown to be only partially effective.[44]

Unacceptable sterilization processes for adequate prion log reduction include gaseous (i.e., ethylene oxide) and physical (e.g., dry heat, boiling, and autoclaving at conventional exposure conditions at 121°C for 15 minutes) processes.[41,44,45,58]Standard gravity displacement steam sterilization at 121°C has been studied with different strains of CJD, BSE, and scrapie and has been shown to be only partially effective, even after exposure times of 120 minutes. As the temperature and exposure time was increased, greater inactivation of the prion agents was achieved.

Several investigators have found that combining sodium hydroxide (0.09 *N*for 2 hours) with steam sterilization at 121°C for 1 hour results in complete inactivation of infectivity (>7.4 logs).[54,58]

However, the use of this mechanism of sterilization in healthcare facilities is problematic because the combination of sodium hydroxide and steam sterilization may be deleterious to surgical instruments and is potentially dangerous to employees exposed to noxious fumes.

Guidelines for Reprocessing Medical Devices Potentially Contaminated with Creutzfeldt-Jakob Disease[24,57,59,60]

High-risk Tissues from High-risk Patients (with Known or Suspected Creutzfeldt-Jakob Disease) and Critical or Semicritical Items

1. Devices that are constructed so that cleaning procedures result in effective tissue removal (e.g., surgical instruments) can be cleaned and sterilized by autoclaving either at 134°C for 18 minutes or longer in a prevacuum sterilizer or at 132°C for 1 hour in a gravity displacement sterilizer.
2. Devices that can be cleaned should be reprocessed by standard published protocols. Place the contaminated items in a container filled with a liquid (e.g., saline, water, or phenolic solution) to retard adherence of organic material to the medical device. Remove any liquids before continuing to the next step, which is an initial decontamination done in an autoclave using 134°C for 18 minutes in a prevacuum sterilizer or 132°C for 1 hour in a gravity displacement sterilizer, or by soaking in 1 *N*sodium hydroxide for 1 hour. Terminal cleaning, wrapping, and sterilization can be done by conventional means. Devices that cannot be cleaned or that are too difficult to clean should be discarded.
3. To minimize drying of tissues and body fluids on the object, instruments should be kept moist until cleaned and decontaminated.
4. Flash sterilization should not be used for reprocessing.
5. Items that permit only low-temperature sterilization (e.g., ethylene oxide or hydrogen peroxide gas plasma) should be discarded.
6. Contaminated items that are not processed according to these recommendations (e.g., medical devices used for brain biopsy before diagnosis) should be recalled and appropriately reprocessed. To minimize patient exposure to neurosurgical instruments from a patient who is later given a diagnosis of CJD, hospitals should consider using the aforementioned sterilization guidelines for neurosurgical instruments used on all patients undergoing brain biopsy. Alternatively, neurosurgical instruments used in such cases could be disposable.

7. Environmental surfaces (noncritical) contaminated with high-risk tissues (e.g., laboratory surface in contact with brain tissue of a person infected with CJD) should be cleaned and then spot-decontaminated with a 1:10 dilution of sodium hypochlorite (i.e., bleach) for a contact time of 15 minutes. To minimize environmental contamination, disposable cover sheets could be used on work surfaces.
8. Noncritical equipment contaminated with high-risk tissue should be cleaned and disinfected with a 1:10 dilution of sodium hypochlorite or 1 *N*sodium hydroxide, depending on material compatibility. All contaminated surfaces must be exposed to the disinfectant.
9. Equipment that requires special prion reprocessing should be identified after use. Clinicians and reprocessing technicians should be thoroughly trained on how to tag the equipment properly and the special prion reprocessing protocols.
10. For ease of cleaning and to minimize percutaneous injury and generation of aerosols, use nonpowered instruments (e.g., drills or saws) or ensure that disposable protective equipment covers are available for powered instruments.

Low-risk Tissues from a High-risk Patient and Critical or Semicritical Medical Devices

1. These devices can be cleaned and either disinfected or sterilized by use of conventional protocols of heat or chemical sterilization or high-level disinfection.
2. Environmental surfaces contaminated with low-risk tissues require only standard disinfectants recommended for bloodborne pathogens by the Occupational Safety and Health Administration (OSHA) for disinfection of blood-contaminated surfaces.

No-risk Tissues from a High-risk Patient and Critical or Semicritical Medical Devices

1. These devices can be cleaned and either disinfected or sterilized by means of conventional protocols of heat or chemical sterilization or by means of high-level disinfection.
2. Endoscopes (except neurosurgical endoscopes) would be contaminated only with no-risk materials, and standard cleaning and high-level disinfection protocols would be adequate for reprocessing.
3. Environmental surfaces contaminated with no-risk tissues or fluids require only standard disinfection (bloodborne pathogen approved) for decontamination of blood-contaminated surfaces (e.g., 1:10 to 1:100 dilution of 5.25 percent sodium hypochlorite). To minimize environmental contamination, disposable cover sheets could be used on work surfaces.

Unrecognized Potential Prion Exposures—Joint Commission Sentinel Event Alert

In 2001, the Joint Commission on Accreditation of Healthcare Organizations, now known as The Joint Commission, received reports of two separate incidents at accredited hospitals in which a total of 14 patients may have been exposed to CJD through instruments used during brain surgeries on patients with unsuspected cases of CJD and issued a Sentinel Event Alert.[61]Lessons learned from sentinel events include the following:

1. A patient with CJD or prion disease does not always present with symptoms of CJD.
2. The time interval between biopsy and pathology report should be monitored and reviewed to ensure the shortest time from biopsy to results.
3. Instruments used in brain biopsy procedures should not be reused when the patient's diagnosis is uncertain at the time of the procedure.

In 2003 one hospital reported an unsuspected case of CJD in a patient who had undergone a craniectomy in the prior year.[62]Operating room instruments were processed in typical fashion (steam

sterilization at 270°F [132°C] for 4 minutes). Eleven months after the surgical procedure, the patient died and an autopsy confirmed CJD. When the diagnosis was confirmed, all operating room instruments underwent immediate prevacuum sterilization at 274°F (134°C) for 18 minutes. In the interim time period, however, the more than 3,600 neurosurgical patients who had undergone surgical procedures were considered to be potentially exposed by the state health department. The incident was fully disclosed to the public, and all patients who were potentially exposed were notified by letter. As a result of this occurrence, this institution mandated that all operating room instruments be routinely processed at 274°F (134°C) for 18 minutes. Potential CJD exposures after an unsuspected case can have an enormous emotional and financial impact. Routine use of extended processing can be implemented to help prevent unintentional CJD exposures. In the future, other large institutions may consider the extended processing in light of cases of prion diseases in the United States and increasing BSEs in Europe.

Conclusions

CJD and other prion diseases of humans and animals represent a unique form of infectious disease that continues to intrigue medical researchers. The number of cases of prion diseases, exclusive of CJD, may continue to increase as exposures from the past decades become manifest in the diseases of the future. The problems presented by the resistance of the physical properties of prion proteins to normal sterilization processes within the medical setting may be met by expanding the limits of technology and introducing new methods to meet the challenge of prion disease.

Future Trends

As the number of cases of prion diseases continues to increase, there is the need for rapid diagnosis, treatment possibilities, and protection of patients through efficacious methods and ease of sterilization and disinfection.

International Perspective

As past exposures become manifest in diseases of the future, concerns regarding CJD and other prion diseases will remain an international concern. Some of those specific concerns include the dura mater grafts in Japan and resultant cases, increased time and temperature settings in autoclaves manufactured in Europe, anticipated increasing numbers of cases, and unknown exposures in Europe with vCJD in the United Kingdom, in particular. The use of leukodepleted blood in some foreign countries as a CJD prevention activity demonstrates the level of international concern with prion disease.

Abstract

Bacterial colonization of the nasopharynx is a common first step in the development of acute bacterial meningitis and many other kinds of infection. The most common etiologic agents of bacterial meningitis are the pneumococci, meningococci, and group B streptococci. Pneumococcal meningitis is age-dependent, with the highest rates occurring at the extremes of age. A primary goal is to determine whether the patient has bacterial meningitis, specifically meningococcus, because there is the need for Transmission-based Precautions, prophylaxis issue for close contacts, and requirements for reporting to public health departments. Most cases of viral aseptic meningitis are benign and self-limited without indications for Transmission-based Precautions. There are evolving issues regarding infections of ventricular shunts, including difficulty in diagnosis, treatment length/route, surveillance, and newer data that antibiotic-impregnated catheters may have some role in reducing infections. Identifying those patients who could have herpes simplex infection is important, because highly effective antiviral treatment is available. Acute encephalitis may reflect infection with bacteria, viruses, rickettsiae, or fungi, or it may be a noninfectious sequel to a prior infection. Arboviruses are important causes of vectorborne encephalitis for which therapy is limited to supportive care. This includes West Nile virus cases, which have recently been reported throughout the United States. Brain abscess is usually the result of direct extension from a bacterial infection such as sinusitis, otitis, mastoiditis, and dental or facial purulent foci. Spinal or cranial epidural abscesses are commonly the result of metastatic spread from regional sites of purulence. Extraordinary infectious particles called prions are the agents responsible for the four spongiform encephalopathies, namely, Creutzfeldt-Jakob disease, kuru, Gerstmann-Sträussler-Scheinker syndrome, and fatal familial insomnia. Most cases of Creutzfeldt-Jakob disease are sporadic, but much attention has focused on the rare occurrence of a new variant form of Creutzfeldt-Jakob disease, which is caused by a transmissible prion that may be spread via organ/tissue transplantation. Although rare, suspected/confirmed Creutzfeldt-Jakob disease cases raise disinfection/sterilization issues for surgical instrumentation.

Key Concepts

- Epidemiology and therapy of bacterial meningitis
- Cerebrospinal fluid shunt infections
- Aseptic meningitis
- Chronic meningitis
- Encephalitis
- Spongiform encephalopathies
- Mycotic aneurysm
- Brain abscess
- Infection prevention and control implications

Background

Central nervous system (CNS) infections may be caused by a variety of agents and manifest with different symptoms and disease processes. Many infections are successfully managed with pharmacological or surgical intervention, some are self-limiting, and a few are untreatable.

Basic Principles

- Meningitis is defined as inflammation of the meninges, the superficial lining tissues of the brain and spinal cord. Common bacteria (e.g., pneumococci, meningococci) or viral pathogens (e.g., herpes simplex virus [HSV], enteroviruses, arboviruses, or mumps) are the usual causes of acute meningitis. Spirochetes (e.g., *Treponema*or *Borrelia*), fungi (*Cryptococcus*or *Candida*), and protozoa (*Naegleria*or *Angiostrongylus*) also may cause acute meningitis. Important diagnostic clues in acute bacterial meningitis are the abrupt or subacute onset of headache, stiff neck, and fever, as well as the presence of inflammatory cells in the cerebrospinal fluid (CSF; especially neutrophils) and positive Gram stain. Distinguish acute bacterial meningitis, especially meningococcus (and to a lesser extent *Haemophilus influenzae*, though this is rare since widespread vaccination), as soon as possible because of the need for isolation, reports to state/local health departments, and prophylaxis to close contacts (a narrowly defined group).
- CSF shunt infections can present a diagnostic dilemma. There are limited data on several aspects regarding these infections, including use of intraventricular instillation, length of treatment, role for surveillance cultures, and routine catheter exchange. Preliminary data support short-course perioperative prophylaxis (preoperatively and first 24 hours) and possible benefits of impregnated intraventricular catheters in preventing infections.
- Encephalitis: Inflammation of the brain may be the result of acute viral infection of brain cells or may reflect a bacterial, fungal, or rickettsial infection, as well as a noninfectious sequel to an earlier systemic infection. Other disease processes, such as malignancy or a rheumatological disorder (e.g., systemic lupus erythematosus), may also produce symptoms of brain inflammation similar to those caused by infectious encephalitis. The defining clinical feature of encephalitis is altered consciousness, but other signs include seizures, abnormal movements, weakness, and, less commonly, sensory deficits. The enteroviruses are the most common causes of encephalitis, and these infections occur mainly in the summer and early fall. Most have no specific treatment. West Nile virus was diagnosed in a patient cluster in the New York City region in 1999, and since then cases

have been seen throughout the United States. Herpes encephalitis is important to consider in the differential diagnosis of patients with encephalitis because diagnostic testing and treatment are available.

- Brain abscess: The majority of brain abscesses occur as the result of direct extension from infections, such as frontal sinusitis, mastoiditis, chronic otitis media, and dental or facial purulent foci. A substantial minority are hematogenous (usually from a cardiac or pulmonary source), and these are often multiple and bilateral.
- Spinal epidural abscess is relatively uncommon, but it occurs in hosts with a broad age range and without gender predominance. Spinal epidural abscesses occur most commonly in the lumbar area, less frequently in the thoracic or cervical area, and least frequently in the sacral region. Infection may be introduced by hematogenous spread from a distant site; by direct extension from vertebral osteomyelitis, perinephric, or psoas abscesses; or by penetrating injuries, paraspinal injections, or spinal surgery. Skin and soft tissue infections are the identified or presumed source in nearly half the cases. On average, three to six contiguous spinal segments are involved. *Staphylococcus aureus*is the most commonly isolated etiologic agent.
- Intracranial epidural abscesses account for approximately 10 percent of all epidural abscesses. In the past, intracranial epidural abscesses were often a consequence of sinusitis, mastoiditis, or otitis media, but recently they most often follow a neurosurgical procedure. Patients with abscess in contiguity with implanted foreign material are at the highest risk.
- Bovine spongiform encephalopathy (BSE): The infectious agent responsible for BSE is a prion, a misfolded version of a normal cellular protein called *PrP*. Prions are self-replicating but devoid of nucleic acid. The particular prion responsible for BSE was probably derived from sheep (in which the infection is known as *scrapie*), although this origin is disputed. BSE is transmissible to humans by ingestion or implantation of infected tissue, and clinically it was recognized as a variant form of neurodegeneration known as new variant Creutzfeldt-Jakob disease (nvCJD). This has implications for cleaning and sterilization of equipment used in neurosurgical procedures for suspected/confirmed cases.
- Four recognized prion-related infections of humans are: kuru, Gerstmann-Sträussler-Scheinker syndrome, fatal familial insomnia (FFI), and CJD. All four are neurodegenerative illnesses with an ultimately fatal course, and there are no effective therapies.
  - Kuru is manifested by loss of motor coordination followed by dementia. It is apparently related to human cannibalism and has been recognized only in the highlands of Papua, New Guinea, where approximately 2,600 cases have occurred since 1957.
  - Gerstmann-Sträussler-Scheinker syndrome is characterized by loss of coordination followed by dementia and death within 2 to 6 years. It is typically familial, and approximately 50 affected families have been identified.
  - CJD is characterized by dementia followed within 1 to 2 months by loss of motor coordination, myoclonus, visual disturbances, hypokinesia, and rigidity. CJD does not usually affect the peripheral nervous system. Most cases are sporadic, but there are cases of iatrogenic nvCJD after dural grafts, corneal transplantation, liver transplantation, administration of human growth or gonadotropic hormones, or use of contaminated neurosurgical instruments or stereotactic electrodes.
  - FFI is characterized by disturbed functions of the autonomic nervous system, insomnia, and dementia. Nine extended families with the syndrome have been reported. The clinical course leading to death is approximately 1 year. FFI, like other prion diseases, is transmissible to experimental animals, and virtually all reported cases have been associated with an asparagine for aspartic acid substitution in the prion protein.

There are significant implications for infection preventionists (IPs) including confirming the appropriate diagnosis to verify that proper infection precautions are put in place and efficient prophylaxis is offered to close or high-risk contacts as appropriate. In most cases no isolation or prophylaxis is needed and reassurance to contacts, including healthcare personnel (HCP), is essential. Emerging pathogens and the risk of iatrogenic introduction (e.g., contamination of medications) of CNS pathogens have introduced new challenges for IPs.

Central Nervous System Infection

MENINGITIS

Meningitis: Etiology and Pathophysiology

Meningitis is defined as inflammation of the meninges, the superficial lining tissues of the brain and spinal cord. Common bacteria such as pneumococci, meningococci, or viral pathogens such as herpes simplex virus (HSV), enteroviruses, arboviruses, or mumps are the usual causes of acute meningitis. Spirochetes (e.g., *Treponema*or *Borrelia*), fungi (*Cryptococcus*or *Candida*), and protozoa (*Naegleria*or *Angiostrongylus*) also may cause acute meningitis.[1]Important diagnostic clues in acute meningitis are the abrupt or subacute onset of headache, stiff neck, and fever, as well as the presence of inflammatory cells in the CSF. Microbial colonization of the nasopharynx is a common first step in the host-parasite relationship that precedes several disparate infections, including acute bacterial meningitis. Many bacterial species express surface receptors that mediate attachment to the host's nasopharyngeal mucosa. After mucosal attachment, pathogens such as meningococci or pneumococci gain access to vacuoles in mucosal epithelial cells and then may enter the blood via regional capillaries. Hematogenous dissemination of microorganisms is followed by invasion of the subarachnoid space and initiation of a diffuse inflammatory reaction of the tissues bathed by the CSF.

Meningitis: Epidemiology

The most common etiologic agents of bacterial meningitis are *Neisseria meningitidis, Streptococcus pneumoniae, Haemophilus influenzae,*group B streptococci, and *Listeria monocytogenes.*Among patients aged more than 50 years and for all immunocompromised patients, the most frequently occurring pathogens are *S. pneumoniae*, *L. monocytogenes,*and aerobic Gram-negative bacilli. Neonates are especially predisposed to infections with group B streptococci and Gram-negative bacilli (e.g., *Klebsiella pneumoniae*or *H. influenzae). N. meningitidis*is the major cause of bacterial meningitis in patients between 2 and 18 years of age.[1,2]

The most significant change in the epidemiology of bacterial meningitis in recent years has been the huge decrease in frequency of *H. influenzae*type b (Hib) meningitis since the introduction of the conjugate *H. influenzae*vaccine in 1987.[1]Before the introduction of effective vaccines, *H. influenzae*was the leading cause of bacterial meningitis in the United States among children younger than 5 years of age. Because of routine use of the Hib conjugate vaccine, the incidence of *H. influenzae*disease in infants and young children has decreased by 99 percent to less than 1 case per 100,000 children aged younger than 5 years. In the United States, *H. influenzae*disease occurs primarily in underimmunized children and among infants too young to have completed the primary immunization series.[3]

Acute Meningitis: Diagnosis, Empiric Antibiotic, and Adjunctive Therapy

The lumbar puncture (LP) is widely recognized as a necessary part of the early diagnostic evaluation of patients with suspected meningitis because the sensitivity of clinical symptoms, including the classic triad of fever, neck stiffness, and altered mental status exam, is low. CSF appearance, opening pressure (taken during this collection by using a simple column manometer; can be used for both for diagnosis and therapeutically), cellularity, biochemical evaluation, and Gram stain provide critically important diagnostic information as well as guidance for therapy.[4]The preliminary CSF findings can provide keys to the diagnosis quickly and guide treatment for the patient and potential need for infection prevention precautions/isolation and prophylaxis for close contacts.[5]Table 74-1 provides some guidelines for the interpretation of the initial CSF findings obtained in acute/subacute meningitis before culture results provide an etiological diagnosis.

Table 74-1. Typical Results of Preliminary Cerebrospinal Fluid Examination in Acute/Subacute Meningitis[2, 5]

Table 74-1 Typical Results of Preliminary Cerebrospinal Fluid Examination in Acute/Subacute Meningitis

Causative Organism	Opening Pressure	Glucose (Ratio of CSF to Serum Glucose)	Predominant Inflammatory Cell	WBC Counts	Total Protein	Staining
Bacteria	Elevated	Normal to decreased	Neutrophils (early or partially treated may have lymphocyte predominance)	≥1,000/mm^3	Elevated(mild to very)	Gram* stain may show GPC or GNC/GNR
Virus	Usually normal	Usually normal	Lymphocytes	<100 per mm^3	Normal to elevated	Gram stain, negative
Fungi	Variable	Low	Lymphocytes	Variable	Elevated	India ink, positive
Tuberculosis	Variable	Low (can be extremely depressed levels)	Lymphocytes	Variable	Elevated	AFB stain, positive

*Positive in 60 to 80 percent of untreated bacterial meningitis/40 to 60 percent of partially treated cases. AFB, acid-fast bacillus (e.g., mycobacterial species); GNC, Gram-negative coccus; GNR, Gram-negative rods (bacillus); GPC, Gram-positive coccus.

Some physicians have adopted a routine policy of performing a computed tomography (CT) scan of the head *before*the diagnostic LP in patients with suspected bacterial meningitis.[6]The rationale for the CT scan is unsuspected, focal, intracranial mass lesions may result in brain stem herniation and even death after an LP because of the creation of a high CSF pressure gradient (lower pressure below the foramen

magnum) between the cranial and spinal CSF compartments after removal of lumbar spinal fluid. Unfortunately, the screening CT scan is often associated with a delay of several hours in the performance of an LP, and the administration of empirical antibiotic therapy (a median of 4 hours in one study from arrival in emergency department and the administration of antibiotics). This delay in treatment can be prevented by administration of antibiotics before the CT scan. However, antibiotic treatment before sampling the CSF may lead to a falsely negative CSF culture. It would be extremely unusual, however, that all the initial CSF studies such as cell count, glucose, protein, and Gram stain would be falsely normal with the administration of this one dose of antibiotics before the LP, even if the antibiotics may inhibit growth on the culture.[2,5]

Clinical studies that help to resolve this dilemma are sparse, but a recently published prospective study of 301 adults with suspected meningitis supports the recommendation that patients with bacterial meningitis should have blood cultures drawn promptly, and if the LP must be delayed, parenteral empirical antibiotic therapy should be initiated immediately.[2,7,8]Experts have suggested that those with new-onset seizure, an immunocompromised state, signs that are suspicious for space occupying lesion, or moderate to severe impaired consciousness should have imaging before LP. An LP may also be harmful in patients with coagulopathy because of the chance of needle-induced subarachnoid hemorrhage or development of a spinal subdural and epidural hematoma.[2]

In these settings the risk and benefit of the LP and delay in treatment will be weighed against the level of suspicion for meningitis and other diagnoses. Although there are scant data on a direct relationship between treatment delay and poor outcome, given the catastrophic potential outcomes from meningitis, empiric treatment in clinically consistent situations is reasonable until additional evaluation and results are obtained. Appropriate antibiotic treatment of most common types of bacterial meningitis should reduce the risk of dying from meningitis to less than 15 percent, although the risk is higher among the elderly.[9]

Empiric (initial) antibiotics for meningitis are based on the most common bacteria causing disease according to the patient's age and clinical setting and on patterns of antimicrobial susceptibility. After the results of culture and susceptibility testing are available, antimicrobial therapy can be modified for optimal treatment. Empiric antibiotic regimens are as follows:[2,10]

- For preterm neonates up to 1 month of age, empiric treatment should have activity against group B streptococcus, most coliforms, and *Listeria*. An acceptable regimen would be ampicillin and cefotaxime.
- For infants 1 month to adults to age 50 years who are immunocompetent, empiric regimen should cover *S. pneumoniae,*meningococcus, and *H. influenzae*(now rare). An acceptable regimen would be cefotaxime or ceftriaxone and vancomycin.
- For adults aged more than 50 years, alcoholics, and those with other debilitating associated disease or impaired cellular immunity, empiric treatment should cover *S. pneumoniae*, *Listeria*, and Gram-negative coverage. An acceptable regimen would be ampicillin and cefotaxime or ceftriaxone and vancomycin.

The issue of whether to use steroids for meningitis or suspected meningitis has been controversial, especially in adults.[2]The value of dexamethasone has been documented in children with *H. influenzae*.[2]

A recent prospective randomized multicenter trial of 301 patients with suspected meningitis in combination with cloudy CSF, bacteria in CSF on Gram staining, or a CSF leukocyte count of more than

1,000/mm^3showed that adjunctive treatment with dexamethasone before or with the first dose of antimicrobial therapy reduced the risk of unfavorable outcome from 25 to 15 percent. Mortality was reduced from 15 to 7 percent. The benefit was greatest in patients with intermediate disease severity (defined by Glasgow Coma Scale) and those with pneumococcal meningitis, in whom unfavorable outcome declined from 52 to 26 percent. In patients with pneumococcal meningitis mortality was reduced from 34 to 14 percent (based on reduced mortality from systemic causes). The benefits of dexamethasone were not offset by side effects of the dexamethasone treatment.[11]

The practical implications of the study are still in evolution; however, most experts agree to the use of steroids for highly suspected/proven pneumococcal meningitis.[2,11,12,13]The issue of empiric treatment for meningitis (because the study used the steroids before or with the first doses of antibiotics) and use in proven bacterial meningitis with other organisms is still controversial. Particularly in some adult patients with suspected meningitis, adjunctive steroids can be harmful (those with septic shock with meningitis).[2, 12]

Meningitis: Acute Bacterial Meningitis (Common)

Acute Meningitis: Pneumococcal Meningitis

*S. pneumoniae*is the most common cause (irrespective of age) of bacterial meningitis in the United States (estimated 2,000 cases/year). A major change in the epidemiology of meningitis has been the worldwide emergence of antimicrobial resistance in *S. pneumoniae*. Rates of penicillin resistance as high as 35 percent have been reported in some geographic areas in the United States (especially the Southeast).**10**,[13]Recently, increasing numbers of pneumococcal isolates have demonstrated resistance to multiple antibiotics; however, pneumococcal resistance to vancomycin has never been described.[13]This explains the rationale for the change in empirical antibiotic choice in the last several years (a combination of ceftriaxone or cefotaxime *and*vancomycin).

After isolation of the causative microorganism and quantitative susceptibility testing, discontinuation of the vancomycin is feasible if the minimum inhibitory concentration of the pneumococcal isolate indicates susceptibility to the chosen third-generation cephalosporin.[13]In addition, the recognition that higher concentration of antibiotics can be achieved in non-CSF sites and by intravenous preparation (vs. oral, particularly for penicillin) has prompted changes in the guidelines that hospital laboratories use for susceptibility testing for pneumococcal isolates ("breakpoint changes").[13]This point is mainly to underscore that the ultimate choices of antibiotics and dosing once an isolate is recovered may be complicated and is often done in consultation with an infectious diseases specialist.

There are currently two types of pneumococcal vaccines: pneumococcal conjugate vaccine (PCV13) and pneumococcal polysaccharide vaccine (PPSV23). The Centers for Disease Control (CDC) Advisory Committee on Immunization Practices (ACIP) recommends that PCV13 be used for all children younger than 5 years of age as a four-dose series beginning at 2 months of age. Children between ages 2 and 5 years who have underlying medical conditions or were not and/or incompletely vaccinated are eligible for supplemental shots with PCV13.

All adults 65 years or older should receive the PPSV23 vaccine, as well as anyone between ages 2 and 64 with chronic medical problems, those that are immunosuppressed, those that smoke, or those that reside in health facilities. Those adults who have not previously received PPV13 should get a dose of

PPV13 first and continue to receive recommended doses of PPSV. The efficacy of Prevnar has been reported as 97.4 percent in preventing invasive pneumococcal disease caused by the seven strains of pneumococcus represented in the vaccine and 93.9 percent efficacy in preventing invasive disease caused by all pneumococcal serotypes. The new vaccine now includes six additional serotypes for added protection.[13]

The risk of pneumococcal meningitis increases at the extremes of age. As with some other meningeal pathogens, pneumococcal infection usually follows recent nasopharyngeal colonization by a virulent strain of pneumococci. Pneumococci have been isolated commonly from the upper respiratory tract of asymptomatic adults. Pneumococcal nasopharyngeal colonization rates are generally higher in children and decline with age. Sickle cell anemia, asplenia, primary or acquired immunodeficiency states, and active or passive exposure to cigarette smoke, as well as cirrhosis, alcoholism, and CSF leak, are risk factors for pneumococcal meningitis.[13]

Acute Meningitis: Meningococcal Meningitis

Each year, an estimated 1,400 to 2,800 cases of meningococcal disease occur in the United States (see **87. Neisseria meningitidis**). *N. meningitidis*causes almost all meningococcal infections and comprises the serogroups A, B, C, Y, and W-135.[9]Serogroup B is the most prevalent in the United States, and this has important implications because of the lack of an effective vaccine against this serogroup.[9,14]The incidence of *Neisseria*infections is greatest in the winter and early spring, and organisms are transmitted from person to person by droplet spread resulting from close contact with a person who is colonized or infected. Asymptomatic nasal carriage of *N. meningitidis*is relatively low in children but may be as high as 25 percent in young adults.[14]

Immunocompromised persons at any age are particularly susceptible to meningococcal infections. Risk factors for meningococcal infection include contact with a carrier, recent viral respiratory infection, and complement deficiency. The mortality rate of isolated meningococcal meningitis is 2 to 5 percent, whereas meningococcal sepsis is a more serious illness with 20 to 40 percent mortality. In addition to meningitis, other complications of meningococcal bacteremia include arthritis, myocarditis, pericarditis, endophthalmitis, and pneumonia.[9,15]

Treatment for meningococcal diseases with high-dose penicillin, ceftriaxone, or cefotaxime is effective against susceptible and even moderately nonsusceptible strains. However, when penicillin is used for treatment, pharyngeal colonization with the infecting *N. meningitidis*strain may persist. Because eradication of meningococcal colonization in the index case protects contacts, the penicillin-treated index patient may need to take rifampin, fluoroquinolone, or cephalosporin to avoid transmission to others.[15]

In addition to high-dose antibiotic administration, adjunctive corticosteroid therapy with dexamethasone (0.15 mg/kg intravenously [IV] every 6 hours for 4 days) has afforded a reduction of neurologic sequelae in multiple studies in children, and some authors recommend it for high-risk adult patients (e.g., those with a high concentration of bacteria in CSF, impaired mental status, cerebral edema, or significantly elevated intracranial pressure).[15,16]

Because close contact with patients with meningococcal disease increases risk for developing infection, even isolated cases can generate severe anxiety to patients' families, as well as school and healthcare personnel who have had recent contact with a patient infected with *N. meningitidis*. The exposed

household, school, or child care contacts must be observed carefully. However, nasal or throat swab cultures are not useful for determining risk (and should not be collected).[9,14,15]

Suspected and confirmed cases of acute meningitis (especially when *N. meningitidis*and *H. influenzae*are of concern) should be placed on Droplet Precautions, and healthcare personnel should use a surgical mask when evaluating these patients until the patient has received a full 24 hours of antibiotics.[15]

Close contacts of all persons with invasive meningococcal infection should receive a prophylactic antibiotic as soon as possible and ideally within hours of the diagnosis of the primary case. The practical issue is to define "close contacts" for both lay persons and healthcare personnel because once even a possible diagnosis of meningitis is entertained it may raise fear and anxiety.

"Close contacts" are defined in Table 74-2 and include household members, child care center contacts, anyone with direct contact with a patient's oral secretions in a personal or professional capacity, or nonhousehold member with shared dwelling and eating.[9,14,15]Thus, most healthcare personnel associated with patients' care will *not*be close contacts because their level of contact with the patient was more casual. Suspected meningitis cases should be placed on droplet isolation. Healthcare personnel who had exposure to patients with the proper personal protective equipment (surgical mask) would not be considered exposed.

Table 74-2. High-Risk Personal Contacts for which Meningococcal Chemoprophylaxis is Recommended[14,15]

Table 74-2 High-Risk Personal Contacts for which Meningococcal Chemoprophylaxis is Recommended

1. Household contacts, especially younger than 2 years of age
2. Child care or preschool contact at any time during 7 days before onset of illness
3. Direct exposure to index patient's secretions through kissing or through sharing toothbrushes or eating utensils, markers of close social contact, at any time during 7 days before onset of illness
4. Mouth-to-mouth resuscitation, unprotected contact during endotracheal intubation during 7 days before onset of illness
5. Frequently slept in same dwelling as index patient during 7 days before onset of illness
6. Passengers seated directly next to the index case during airline flights lasting more than 8 hours

The attack rate for household contacts exposed to patients who have meningococcal disease was estimated as 4 cases/100 persons exposed (500 to 800 times the rate for the total population and many times higher than that of healthcare personnel).[14]Because the rate of secondary disease for close contact is highest immediately after onset of diseases in the index patients, antimicrobial prophylaxis should be administered as soon as possible within 24 hours of diagnosis of the primary case but may be given up to 10 to 14 days after contact (chemoprophylaxis administered >14 days after exposure is probably of limited or no value).[14,15,16]However, it is important to underscore that there is time for at least the initial evaluation of the index patient. Often the clinical presentation, CSF initial testing (including Gram stain), and clinical suspicion of those caring and providing consultation for the patient are key. Not all cases are meningitis, and not all bacterial meningitis cases require mobilizing resources to prophylaxis of close contacts. Discerning likely aseptic viral meningitis is important.

Recommended regimens for antibiotic chemoprophylaxis in adults include rifampin, ciprofloxacin, or ceftriaxone, all of which are 90 to 95 percent effective in reducing nasopharyngeal carriage of *N. meningitidis*(Table 74-2).[15]Ciprofloxacin (500 mg by mouth) is especially a favored regimen in

nonpregnant adults, because it is oral and requires only one dose. Azithromycin is an acceptable alternative but not recommended routinely.

A recent *Morbidity and Mortality Weekly Report*described a cluster of three cases of serogroup B, fluoroquinolone-resistant meningococcal disease that occurred among residents of the border area of North Dakota and Minnesota during 2007 and 2008.[17]The first of these cases was epidemiologically linked and closely molecularly related to a 2006 case with the same resistance occurring in the same geographical area. The report recommended a change in chemoprophylaxis for contacts of meningococcal diseases in that limited geographic region and vigilance/surveillance for resistance in other areas. Other case reports have documented rifampin resistance. These isolated cases illustrate the need to perform appropriate susceptibility testing on meningococcal isolates. Thus, there are no other general recommendations to change prophylaxis from the regimens described above.

More than 98 percent of meningococcal disease cases in the United States are sporadic, whereas the other 2 percent are associated with outbreaks.[14]Multiple studies have illustrated a higher risk of meningococcal disease among college students, particularly those who reside in dormitories. Several recent outbreaks have been in this college setting (13 [26 percent] of 50 outbreaks within organized facilities during 1994 to 2002 were in colleges).[14]In 2000, the ACIP recommended that college students/parents be informed of the risk of meningococcal diseases and potential benefit to vaccination (described below).[16]

There are two meningococcal vaccinations currently available.[9,16]The tetravalent meningococcal polysaccharide vaccine, MPV4 (Menomune-A/C/Y/W135; Sanofi Pasteur, Swiftwater, PA) has been available since the 1970s and has been used in mass vaccination among international travelers and the military. Usefulness is now more limited because it does not confer long-lasting immunity and does not cause sustainable reduced nasopharyngeal carriage.

A tetravalent meningococcal conjugate vaccine, MCV4 (Menactra, Sanofi Pasteur, Lyon, France) was licensed in January 2005 for persons aged 11 to 55 years. The vaccination is for those aged 11 to 12 years, before entry to high school, college freshmen living in dorms, and other populations at risk (microbiologist with exposure, military, travelers, those with terminal complement deficiencies and anatomic/functionally asplenic) and has more recently been used in certain outbreak settings.[16]

The decision to implement mass vaccination to prevent meningococcal disease in college or other settings is complicated and would involve public health officials. Details such as the number of cases, attack rate, serogroup and typing, cost, feasibility, and potential for antimicrobial resistance development would be some of the key factors weighed. Other controls, such as closures, travel restrictions, canceling of congregate events, are also part of the control plans.[14,16]

Cases of suspected and confirmed meningococcal disease are reportable to most state and local public health departments. This allows for proper identification and prophylaxis of close contacts, surveillance for clusters/outbreaks and vaccine failures, laboratory aid including susceptibility testing, sero-grouping and typing, and proper information/communication with public (as previously discussed).[16]

Acute Meningitis: Cerebrospinal Fluid Shunt Infections

CSF shunts are used in the setting of hydrocephalus to divert CSF to another part of the body for absorption. There are several controversies (areas without clear data) in the management of shunt

infections.[18]

The rate of CNS shunt infection is approximately 5 to 15 percent.[18]Risk factors include intraventricular hemorrhage, subarachnoid hemorrhage, and cranial fracture with CSF leak.[18,19,20]Fever, headache, nausea, lethargy, and mental status changes are common, but the acuity of signs and symptoms may vary depending on the microbial cause. Clinical manifestations may be subtle or absent. They may present as manifestations of increased intracranial pressure or with symptoms localized to the distal end of the device.

CT or magnetic resonance imaging (MRI) scans of the head are especially indicated if there are clinical signs of a mass lesion or elevated CSF pressure. Signs of meningitis or ventriculitis are indications for sampling of CSF from the shunt reservoir (preferred over ventricular tap or lumbar puncture when possible), and this should be performed with careful attention to sterile technique. Both blood and CSF bacteriologic cultures should be obtained. Gram stain and culture as well as differential cell count, glucose, and protein determinations should be performed on the CSF. Although interpretation of CSF can be challenging, the white cell differential may be a useful clue.[18,19,20]In one report of 129 shunt placements, a differential with 0.10 percent neutrophils was 90 percent sensitive in predicting infection and had a negative predictive value of 0.99.[20]

Skin flora account for the majority of infections associated with internalized or externalized CNS shunt devices. Shunt infections may also develop from the distal ends of internalized devices, leading to peritonitis or bacteremia with a variety of pathogens.[18]There are no randomized, prospective trials addressing optimal treatment of CNS shunt infections. Management should include removal of the device, external drainage, parenteral antibiotics, and shunt replacement (when CSF is sterile). Empiric parenteral therapy should cover Gram-positive pathogens (especially coagulase-negative *Staphylococcus*) and healthcare-associated Gram-negative organisms. Regimens such as parenteral vancomycin plus an antipseudomonal cephalosporin or carbapenem would be acceptable. Regimens can be narrowed on the basis of CSF cultures. The duration of antibiotic therapy depends on the implicated pathogen and presence of retained hardware.[18]

There have been limited trials evaluating the clinical efficacy of intraventricular antibiotics. There has been one randomized trial studying the inflammatory markers in the CSF of 21 neonates with Gram-negative bacilli meningitis and ventriculitis which demonstrated increased inflammatory markers in the group that received intraventricular antibiotics compared to the group that received parenteral antibiotic therapy alone. This may suggest a poorer outcome in those who receive intraventricular antibiotics. It may be useful when parenteral antibiotics fail to sterilize the CSF, with antimicrobial resistance (where susceptible antibiotics are those with poor CSF penetration) or where devices cannot be removed. There are no antibiotics that are U.S. Food and Drug Administration approved for intraventricular use and no standardized dose. The most clinical experience has been with vancomycin and gentamicin.[18]

Routine prospective CSF analysis has little value in predicting infection and may increase the risk of iatrogenic infection.[18]Some favor surveillance CSF analysis when the predisposing diagnosis is associated with an increased risk of infection, such as subarachnoid or intraventricular hemorrhage or cranial fracture. Others advocate for CSF analysis only when infection is suspected on clinical grounds.[18]

Another area of controversy is perioperative prophylaxis.[18,20,21,22] There are no randomized trials, but a recent meta-analysis of 15 observational studies concluded that use of systemic prophylaxis antibiotics before placement and for the initial 24 hours after device placement decreases rates of shunt infection.[21]

Antibiotic-impregnated catheters have shown some promise in reducing the incidence of CNS shunt infections. In a randomized trial of 288 device placements, patients with antibiotic-impregnated catheters were less likely to develop positive CSF cultures than those who received control catheters.[23] A meta-analysis showed reduction of shunt infections with impregnated catheters.[21] Prophylactic catheter change is not effective for preventing CNS shunt infection and is not recommended.[18]

Acute Meningitis: Aseptic Meningitis

Aseptic meningitis is defined broadly as meningeal inflammation that is *not* due to bacteria or fungi.[24] Viral pathogens are only one of several etiological categories[24] (reviewed in Table 74-3).

From a practical point of view, distinguishing these cases from bacterial meningitis as soon as possible is important. First, from an infection prevention perspective, Transmission-based Precautions are not indicated for cases of aseptic meningitis as they are for bacterial meningitis. In addition, aseptic meningitis is usually less severe than bacterial meningitis and rarely fatal, a fact that can be underscored to the public and the healthcare personnel at risk of exposure. Most cases are self-limited and do not require specific treatment. There is also no special prophylaxis for close contacts.[25]

Table 74-3. Differential Diagnosis of Aseptic Meningitis[24]

Table 74-3 Differential Diagnosis of Aseptic Meningitis

1. Viral infections (enteroviruses, mumps, arboviruses, lymphocytic choriomeningitis virus, herpes simplex, varicella-zoster, adenoviruses, Epstein-Barr virus, parvovirus B19)
2. Nonviral infections (partially treated bacterial meningitis, parameningeal infections, brain abscess, spirochetal or fungal infections, tuberculosis, toxoplasmosis, rickettsial infections, *Mycoplasma pneumoniae*, cat scratch disease, and amebic meningoencephalitis)
3. Noninfectious etiologies include ingestion of nonsteroidal anti-inflammatory drugs, brain tumor, carcinomatous meningitis, intrathecal drugs, radiographic dyes, lead poisoning, and benign intracranial hypertension
4. Unknown etiologies include Kawasaki disease and Mollaret syndrome

Acute Meningitis: Viral Meningitis

Viral aseptic meningitis is the most common infectious disease involving the CNS.[25,26] Epidemiologic studies reveal that it is more common in males than females and approximately four times more common in children who are 1 year of age or older. Clinical features occurring in older children include headache, fever, irritability, nuchal rigidity, nausea, and vomiting. However, cases may also occur in infants aged less than 2 to 3 months of age. In neonates (2 weeks), enteroviral meningitis may be a devastating illness. A bulging anterior fontanel and nuchal rigidity may be combined with vomiting, anorexia, rash, and upper respiratory signs and symptoms. Beyond the neonatal period, severe disease and poor outcomes are rare.

Acute Meningitis: Enteroviruses and Human Immunodeficiency Virus

The most common causes of viral aseptic meningitis in the United States are lymphocytic choriomeningitis virus and coxsackie B viruses. Aseptic meningitis is less frequently caused by echoviruses or coxsackie A virus.[26]Particular clinical stigmata are associated with certain enteroviral serotypes. For example, echovirus 9 is associated with maculopapular rashes. Painful vesicles on the posterior pharynx are seen with coxsackievirus A, and the presence of pericarditis or pleurisy suggests coxsackie B virus. The peak occurrence of viral aseptic meningitis is in July, August, and September with a nadir in early spring. Despite significant short-term morbidity, there is little evidence of long-term neurologic or developmental sequelae. Pleconaril, a novel, oral, systemically active, small molecule inhibitor of enteroviruses and rhinoviruses, has been shown to shorten the course of illness compared to placebo, especially early in the disease course.[27,28,29]A unique clinical situation is seen in children and adults with humoral immune deficiency because of their inability to mount adequate enteroviral immunity. For example, patients with agammaglobulinemia develop a chronic or recurrent enteroviral meningitis and meningoencephalitis that may last several years with a fatal outcome or may even relapse and recur over decades.[24]Other patients may present with typical aseptic meningitis symptoms caused by acute human immunodeficiency virus (HIV) infection. When this occurs, the patients may be unaware of their recently acquired HIV infection. Therefore, elements of the history related to intravenous drug use or possible sexually transmitted infection should be elicited. The most common clinical features are headache, fever, and meningeal signs. The symptomatic illness is self-limited but may be recurrent. When HIV infection is considered in this setting it may be important to request that a viral polymerase chain reaction (PCR) assay be performed on CSF or blood.[24]

CHRONIC MENINGITIS

It is often difficult to distinguish chronic meningitis from the more common forms of acute meningitis or encephalitis. A widely accepted but arbitrary definition of chronic meningitis is one in which neurological signs or symptoms persist or progress and the CSF remains abnormal for at least 4 weeks. This category of illness is problematic, and a large fraction of patients with chronic meningitis remain without an etiological diagnosis even after extensive and systematic evaluation. The agents of chronic infections such as tuberculosis, syphilis, histoplasmosis, Lyme disease, cryptococcosis, candidiasis, brucellosis, and other less common infectious and noninfectious etiologies may also cause chronic meningitis. Diagnostic physical findings are rare, and the cause ultimately must be established in the laboratory. Noninfectious causes of chronic meningitis include sarcoidosis, Behçet disease, neoplasms, granulomatous angiitis, uveomeningoencephalitis, and chronic benign lymphocytic meningitis. Serological studies of blood and CSF are very important in evaluating the patient with chronic meningitis. Tests for cryptococcal antigen and for antibodies to *Brucella, Histoplasma, Toxoplasma, Sporothrix,*and *Treponema*should be performed routinely. Gripshover and Ellner[30]have written an extensive review and discussion of this difficult diagnostic and therapeutic problem.

ENCEPHALITIS

Acute Encephalitis

Inflammation of the brain may be the result of acute viral infection of brain cells or may reflect a bacterial, fungal, or rickettsial infection, as well as a noninfectious sequel to an earlier systemic infection. Other disease processes such as malignancy or a rheumatological disorder (e.g., systemic lupus erythematosus) may also produce symptoms of brain inflammation similar to those caused by infectious encephalitis. The defining clinical feature of encephalitis is altered consciousness, but other signs include seizures, abnormal movements, weakness, and, less commonly, sensory deficits. The

enteroviruses (Table 74-4) are the most common causes of encephalitis, and these infections occur mainly in the summer and early fall. Some organisms produce symptoms typical of both encephalitis and meningitis, resulting in syndromes termed *meningoencephalitis*.[31]

Table 74-4. Human Encephalitis Viruses Occurring in the United States (Modified after Storch[31])

Table 74-4 Human Encephalitis Viruses Occurring in the United States (Modified after Storch

Herpes viruses	Herpes simplex Varicella-zoster Epstein-Barr Cytomegalovirus Human herpesvirus 6 Herpes B virus
Arthropodborne viruses	St. Louis encephalitis Eastern equine encephalitis Western equine encephalitis California encephalitis group West Nile encephalitis
Enteroviruses	Echovirus Coxsackievirus Poliovirus
"Childhood disease" viruses	Mumps Measles Rubella
Respiratory disease viruses	Influenza Parainfluenza Adenovirus
Rabies	
Lymphocytic choriomeningitis virus	
Human immunodeficiency virus (HIV)	
Jamestown Canyon (JC) virus	

Diagnostic Studies

It should be a primary goal to determine if the patient with encephalitis could have HSV as the etiologic agent. The reasons for the primacy of HSV in the differential diagnosis are as follows: (1) it is relatively common; (2) treatment usually improves the outcome; and (3) the treatment of choice (acyclovir or its congeners) is effective and well tolerated by most individuals.[32,33]Encephalitis syndromes that are due to most other etiologic agents do not share these encouraging characteristics. An LP with measurement of opening pressure and routine CSF studies (e.g., cell count, routine chemistries, as well as Venereal Disease Reference Laboratory [VDRL], Gram stain, bacterial and fungal cultures, and cryptococcal antigen assay) should be performed on CSF from cases of suspected encephalitis.

CSF also should be submitted for viral culture or PCR assays (e.g., HSV, cytomegalovirus, varicella-zoster virus [VZV], Epstein-Barr virus, and enteroviruses).[34,35]PCR assays are also available to detect HIV, JC virus (John Cunningham virus), and an increasing number of other microbial pathogens. The quality, including the sensitivity and specificity, can vary based on the lab.[34,35]

Epidemiology

Epidemiologic characteristics of the encephalitis syndrome may help to confirm certain etiologies such as rabies (bite wounds or contact with wild animals including bats). A history of patient contact with horses, other animals, or knowledge of local outbreaks of encephalitis (e.g., information from the state or local health departments about the current prevalence of West Nile virus infections) may provide support for consideration of arthropodborne (usually mosquitoes in the United States) or enteroviral encephalitis. Careful questioning of the parents of a child with signs of encephalitis will generally encourage or exclude serious consideration of measles, mumps, rubella, as well as recent respiratory illness compatible with influenza, parainfluenza, or adenovirus, as potential causes of viral encephalitis.

Most states require reporting suspected or confirmed cases of viral encephalitis to state and local health departments. These entities may be able to offer additional CSF testing for specific etiology through referral laboratories. In addition, surveillance or public health action may be needed. For example, for West Nile virus cases, a search for reservoirs for the mosquito vectors that carry the virus is performed in the vicinity of the index patient's home and travel in attempt to prevent transmission to other vulnerable hosts. Public information about other protective measures, such as use of insect repellents and removal of stagnant water, is also shared during the times West Nile virus activity is noted (in the Northeast during later summer/early fall).

Herpes Simplex-1

HSV-1 (the commonly recurrent mouth or "cold sore" virus) is the most common cause of acute, nonepidemic viral encephalitis in the United States. There is no seasonal predilection. Active infection with HSV-1 usually occurs because of endogenous latent viral reactivation. The clinical onset is typically sudden but occasionally it may be subacute. HSV-1 has a tropism for the medial, temporal, and inferior frontal lobes of the brain. The resulting symptoms include headache, fever, gustatory or olfactory hallucinations, and bizarre behavior. Accompanying herpes labialis ("cold sore") is seen in less than 10 percent of cases. This contrasts with the common but not uniform occurrence of mucocutaneous lesions in HSV-2 meningitis (vagina, perirectal area, or mouth).[32]Head CT scanning or MRI can aid in the diagnosis of HSV-1 encephalitis if typical focal brain lesions are revealed. PCR testing for HSV can be obtained, supporting the diagnosis.[33]Treatment with acyclovir (10 mg/kg IV every 8 hours for 10 to 14 days) can significantly reduce the morbidity and mortality of this infection, unless the patient is comatose at the onset of therapy. Given that this is one of the rare treatable encephalitis diagnoses, empiric treatment may be started while awaiting testing. For patients with CNS symptoms of HSV only (not skin or other manifestations), there are no specific isolation requirements.

Arboviruses

The arboviruses seen in North America include the causative agents of California, St. Louis, West Nile, Venezuelan equine, and Western or Eastern equine encephalitides.[35]Each of these viral infections may produce a clinically indistinguishable syndrome of acute headache, fever, and mental status changes, occurring mainly in the summer. They are vectorborne by mosquitoes or ticks, and the etiological diagnosis is usually made by an increasing antibody titer specific for the etiologic virus in the comparison of acute and convalescent sera from the affected patient. There is no specific treatment for any member of this group.

Japanese Encephalitis

This infection is caused by a flavivirus that is endemic to India and Japan, where it is a major public health problem. Mosquitoes transmit Japanese encephalitis, and it may occur in tourists who spend

prolonged periods in rural regions of Southeast Asia. The diagnosis can be confirmed by detection of Japanese encephalitis virus immunoglobulin M antibodies in the CSF. There is no specific treatment, but a safe and effective vaccine is available.[35]

Varicella-zoster Virus

This form of encephalitis usually occurs as a complication of clinically evident chickenpox. CNS involvement develops at the end of the first week of the exanthem. The most frequent manifestation is acute cerebellar ataxia, but the clinical spectrum may range from meningitis to diffuse encephalitis. Encephalitis may also rarely occur during clinically disseminated VZV (with typical rash). In these cases airborne isolation is needed for a hospitalized patient. Treatment with acyclovir has been used in severe cases with some success.

West Nile Virus

West Nile virus, a mosquitoborne flavivirus, was first isolated from a febrile patient in the West Nile Region of Uganda in 1937. It remained sporadic encephalitis in Africa, Europe, and Asia until its surprise detection in the New York City region in 1999. In the last few years, cases have been seen throughout the United States, including the West Coast.[36,37]Nearly all infections result from mosquito bites; however, transmission via breast milk, transmission through transplanted organs and transfused blood, and occupational transmission by means of percutaneous exposure have occurred.[36]West Nile virus may have a wide range of presentations with neuroinvasive syndromes (West Nile encephalitis, West Nile meningitis, or West Nile meningoencephalitis) and West Nile fever (a less severe viral syndrome characterized by fever, headache, tiredness, aches, and sometimes rash), and many patients will be asymptomatic. People aged more than 50 years and the immunosuppressed (transplant recipients) are at higher risk for severe disease. There is no specific treatment for West Nile virus.[34]

BRAIN ABSCESS

Pathophysiology

The majority of brain abscesses occur as the result of direct extension from infections, such as frontal sinusitis, mastoiditis, chronic otitis media, and dental or facial purulent foci.[37]See Table 74-5. A substantial minority are hematogenous (usually from a cardiac or pulmonary source), and these are often multiple and bilateral.

Chronic sinusitis-related brain abscesses occur mainly in young to middle-aged adults, and they are typically polymicrobial, yielding anaerobic and aerobic bacterial species. Osteomyelitis of the posterior wall of the frontal sinus may cause simultaneous epidural abscess, frontal lobe brain abscess, or subdural empyema. Temporal lobe abscesses are often a complication of purulent otitis media, and they usually yield multiple organisms, including streptococci, *Bacteroides*spp., and aerobic Gram-negative bacilli. Brain abscess occurring as a complication of facial infection often develops through intervening septic thrombophlebitis. Facial injury may seem trivial; for example, a pencil point or other sharp object may penetrate the orbital wall and be detected only after a long latent period (even several years) with the onset of seizures caused by an encapsulated frontal lobe abscess. Approximately one-third of brain abscesses arise by hematogenous spread from a distant primary focus. These usually have a pulmonary origin (lung abscess, bronchiectasis) or a cardiac origin (*S. aureus*endocarditis of aortic or mitral valves or tricuspid endocarditis with a right-to-left cardiac shunt).[37]

Table 74-5. Microbial Etiologies of Brain Abscess[37]

Table 74-5 Microbial Etiologies of Brain Abscess

Organisms	Total (%)
Staphylococcus aureus	92 (13.4)
Gram-negative bacilli (aerobic)	108 (15.7)
Streptococci	220 (32.1)
Anaerobic streptococci	66 (9.6)
*Bacteroides*spp. Group	74 (10.8)
Other bacteria (*Listeria*spp., *Mycobacteria*, etc.)	80 (11.7)
Fungi, protozoa (*Cryptococcus, Candida, Toxoplasma,*etc.)	46 (6.7)
Total	686 (100)

Clinical Features

Brain abscesses may occur at any age but are rare in infancy. The peak incidence is usually between 40 and 50 years old and is predominant in males. Almost all patients with brain abscess will give a history of headache and fever, but focal neurological abnormalities are often absent. Occasionally, patients will have a history of progressive obtundation, seizure activity, or focal neurological findings. Somnolence, vomiting, and third or sixth cranial nerve palsies are common. Papilledema is an important and often late sign that should prompt immediate head imaging (MRI or CT scan) and neurosurgical evaluation. The symptom course of a brain abscess may extend over several weeks or even months, but a hematogenous brain abscess caused by virulent organisms (e.g., *S. aureus*) may have a fulminant course with high fever and death in 2 weeks or less. Successful treatment usually requires surgery plus antibiotic therapy. Patients with rapidly progressing symptoms may even present with pyogenic meningitis (headache, high fever, and a stiff neck) from brain abscess rupture into the subarachnoid space.[37]

EPIDURAL AND SUBDURAL ABSCESSES

Epidural Abscess: Anatomy

The epidural space is a true or potential space bounded by the dura and the adjacent cranial or vertebral bones. It surrounds both the brain and the spinal cord. However, the posterior epidural space below the foramen magnum is a true anatomic space containing fat and blood vessels, whereas the entire cranial and the *anterior*spinal epidural spaces are only potential spaces with dura firmly adherent to bone. This anatomic difference results in the much higher frequency of posterior spinal epidural abscesses.

Epidural Abscess: Spinal Epidural Abscess

This condition is relatively uncommon, but it occurs in hosts with a broad age range and without gender predominance. Seventy percent of cases present with abscess formation in the posterior space between the dura and the vertebral bodies. Spinal epidural abscesses occur most commonly in the lumbar area, less frequently in the thoracic or cervical area, and least frequently in the sacral region. Infection may be introduced by hematogenous spread from a distant site, by direct extension from vertebral

osteomyelitis, perinephric or psoas abscesses, or by penetrating injuries, paraspinal injections, or spinal surgery. Skin and soft tissue infections are the identified or presumed source in nearly half the cases. On average, three to six contiguous spinal segments are involved. *S. aureus*is the most commonly isolated etiologic agent.[38,39]

Epidural Abscess: Symptom Progression in Spinal Epidural Abscess

The four-stage clinical classification based on the sequential occurrence of signs and symptoms caused by spinal epidural abscess is widely accepted.[38]See Table 74-6.

Table 74-6. Clinical Progression of Signs and Symptoms of Spinal Epidural Abscess[38]

Table 74-6 Clinical Progression of Signs and Symptoms of Spinal Epidural Abscess

Stage 1. Back pain and tenderness
Stage 2. Nerve root pain, radiculopathy, tendon reflex changes
Stage 3. Motor weakness, sensory deficits
Stage 4. Paralysis

Stages 1 and 2 may be evident for longer periods but usually last only 3 to 4 days and are followed 4 to 5 days later by complete paralysis, which may quickly become irreversible even with adequate surgical drainage and appropriate antimicrobial therapy. Patients whose symptoms/signs progress rapidly through the early stages and all those exhibiting stage 3 to 4 signs should be regarded as neurological emergencies, evaluated radiologically (usually by MRI of the spine), and considered for immediate surgical drainage. A delay in the diagnosis after the development of neurological dysfunction is usually responsible for poor outcomes.[38]Patients with a more acute development of spinal epidural abscess will usually have fever, leukocytosis, and an elevated erythrocyte sedimentation rate (ESR). Blood cultures obtained before antibiotic therapy often will reveal the etiologic bacterium (50 to 70 percent of cases), but intraoperative cultures of the abscess contents have the highest yield and the greatest significance. Lumbar puncture and CSF examination usually are not very helpful.[38]

Published case series have noted that "spinal epidural abscess" was frequently absent from the differential diagnosis on admission of the patient to the hospital. The most common incorrect clinical diagnoses are trauma, degenerative joint disease, musculoskeletal pain, vertebral osteomyelitis, tuberculosis of the spine, or metastatic neoplasia. In addition to surgical drainage and debridement, treatment of spinal epidural abscess should include prolonged parenteral antibiotic therapy (4 to 8 weeks, depending on the adequacy of surgical drainage, clinical response, and the presence or absence of osteomyelitis). When *empirical*antibiotic therapy is elected, it should always include an appropriate antistaphylococcal agent (e.g., ampicillin/sulbactam, oxacillin, nafcillin, or vancomycin especially in areas with high rates of methicillin-resistant S. *aureus*), with additional antimicrobials when there are clinical clues suggesting a particular anatomic site (e.g., cefepime or ceftriaxone if there is evidence of a renal origin of the spinal infection).

Epidural Abscess: Intracranial Epidural Abscess

Intracranial epidural abscesses account for approximately 10 percent of all epidural abscesses.[37]In older published reports, intracranial epidural abscesses were often noted to be a consequence of sinusitis, mastoiditis, or otitis media, but in recent case series they most often follow a neurosurgical procedure.

Patients with abscess in contiguity with implanted foreign material are at the highest risk. Above the foramen magnum, the dura comprises the inner lining of the skull, and the epidural space is only a potential space. Consequently, epidural intracranial infections result mainly from extension of contiguous infections, such as sinusitis, orbital cellulitis, and rhinocerebral mucormycosis, or as complications of traumatic skull fracture, neurosurgical procedure, or intracranial fetal monitoring. An intracranial epidural abscess generally expands slowly, dissecting the dura away from the inner table of the skull. The causative organisms are usually those associated with the primary infection. For example, those originating in the paranasal sinuses are generally caused by hemolytic streptococci and anaerobes (*Propionibacterium*and *Peptococcus*spp.), whereas those associated with penetrating trauma are *S. aureus*or coagulase-negative staphylococci. The organisms responsible for mucormycosis are the Zygomycetes (*Mucor, Absidia, Rhizopus*spp.). These fungal infections usually originate in the paranasal sinuses or the retro-orbital space, and the typical host is a diabetic presenting with acidosis and a focal invasive cranial infection. The symptoms of cranial epidural abscess may be nonspecific, such as fever, headache, nausea, vomiting, and lethargy. These may have been present for several weeks or even months and may be misinterpreted as reflecting only the primary process (e.g., sinusitis or even a recent traumatic skull fracture) before head imaging is obtained and a diagnosis of epidural abscess is made. Hyponatremia may occur in 30 percent of patients, serving as a clue to the discovery of an intracranial inflammatory mass. An important complication of cranial epidural abscess is the development of thrombosis of the valveless emissary veins between the skull and the meninges. This may lead to the development of a subdural empyema, meningitis, or brain abscess complicating the epidural abscess.

CT or MRI scanning of the head can establish the diagnosis of cranial epidural abscess. The therapy is fundamentally the same as for spinal epidural abscess, namely, a combination of neurosurgical drainage and the parenteral administration of appropriate antibiotics. If the dura is not destroyed, simple debridement is often satisfactory and can provide the necessary microbiological sampling for culture and susceptibility testing that permits the appropriate choice of antibiotic agents.

TRANSMISSIBLE SPONGIFORM ENCEPHALOPATHIES

Spongiform Encephalopathy: Bovine Spongiform Encephalopathy

A recent epidemic of BSE (see **73. Creutzfeldt-Jakob Disease and Other Prion Diseases**) began in the United Kingdom in 1986 and affected approximately 200,000 cattle.[39]The infectious agent

responsible for BSE is a prion, a misfolded version of a normal cellular protein called *PrP*. Prions are self-replicating but devoid of nucleic acid. The particular prion responsible for BSE was probably derived from sheep (in which the infection is known as *scrapie*), although this origin is disputed. BSE is transmissible to humans by ingestion or implantation of infected tissue, and clinically it was recognized as a variant form of neurodegeneration known as new variant Creutzfeldt-Jakob Disease (nvCJD).[40]It

was later shown that iatrogenic nvCJD occurred after the transplantation of infected dura mater, pituitary, or eye tissues. Notably, the latent period between graft placement (e.g., dura) and the onset of symptoms of nvCJD may be as long as 22 years.[41]

Human cases of nvCJD have major distinguishing clinical and pathophysiological features (a younger age of onset than classic CJD and the presence of distinctive amyloid as found in all 76 patients with nvCJD who were tested).[42]The link between cattle with BSE and the distinctive molecular and biological

features of nvCJD has been convincingly established.[43,44,45,46]The source of infection is believed to be

ingestion of beef contaminated by nervous system tissue (probably residue of spinal cord or paraspinal ganglia). The first case of nvCJD was recognized in 1994, nearly a decade after BSE was described in

cattle. This incubation period of infection is consistent with experimental infections in animals and iatrogenic nvCJD in humans.[42,43,44] Exposure of medical and surgical instruments to what is possibly infectious human tissue and the transfer of tissue as grafts and transplants has become a matter of great concern, more so than the nearly negligible risk posed by cases of sporadic CJD.[45,46,47]

Spongiform Encephalopathy: Human Prion Diseases

This topic was reviewed by Prusiner (the discoverer of prions), a leading investigator in the field.[48] There are four recognized prion-related infections of humans: kuru, Gerstmann-Sträussler-Scheinker syndrome, FFI, and CJD. All four are neurodegenerative illnesses with an ultimately fatal course and there are no effective therapies. See also **73. Creutzfeldt-Jakob Disease and Other Prion Diseases**.

Kuru is manifested by loss of motor coordination followed by dementia. It is apparently related to human cannibalism and has been recognized only in the highlands of Papua, New Guinea, where approximately 2,600 cases have occurred since 1957. The duration of overt illness before death is usually 3 to 12 months.[48]

Gerstmann-Sträussler-Scheinker syndrome is characterized by loss of coordination followed by dementia and death within 2 to 6 years. It is typically familial, and approximately 50 affected families have been identified.[48]

CJD is characterized by dementia followed within 1 to 2 months by loss of motor coordination, myoclonus, visual disturbances, hypokinesia, and rigidity. CJD does not usually affect the peripheral nervous system. Most cases are sporadic, but there are cases of iatrogenic nvCJD after dural grafts, corneal transplantation, liver transplantation, the administration of human growth or gonadotropic hormones, or the use of contaminated neurosurgical instruments or stereotactic electrodes.[48] In 10 to 15 percent of cases there is familial inheritance of a mutation of the prion protein gene. Laboratory diagnostic testing is rarely helpful in CJD, but some patients have elevated serum levels of S100 protein or an elevated "14–3-3" protein in the CSF.[49,50] The clinical course leading to death is typically approximately 1 year.

FFI is characterized by disturbed functions of the autonomic nervous system, insomnia, and dementia. Nine extended families with the syndrome have been reported. The clinical course leading to death is approximately 1 year. FFI, like other prion diseases, is transmissible to experimental animals, and virtually all reported cases have been associated with an asparagine for aspartic acid substitution in the prion protein.[48,51]

Spongiform Encephalopathy: Preventing the Spread of New Variant Form of Creutzfeldt-Jakob Disease

Iatrogenic transmission of the CJD agent has been reported in more than 250 patients worldwide.[45]

These cases have been linked to use of contaminated human growth hormone, dura mater and corneal grafts, or neurosurgical equipment. Of the six cases linked to the use of contaminated equipment, four were associated with neurosurgical instruments and two were associated with stereotactic electroencephalogram depth electrodes. All these occurred before the routine implementation of sterilization procedures currently used in healthcare facilities. No such cases have been reported since or from surfaces such as floors, walls, or countertops.[45]

Disposable instruments should be used whenever possible on patients with suspected or confirmed CJD. A standard sterilization protocol for reusable instruments should be implemented, which includes the most stringent disinfection possible (e.g., the combined use of 1N sodium hydroxide and autoclaving at 134°C) as recommended in recent World Health Organization guidelines on infection prevention for CJD.[45,46]No effective sterilization procedure exists for instruments that are too delicate to withstand these harsh procedures. Notably, prions may be extraordinarily heat resistant. In experiments with the hamster-adapted scrapie agent, prions remained infectious after heating to ash at 600°C but not when heated to 1,000°C.[52]Surgical instruments should be disinfected to the maximum extent possible, for example, by washing repeatedly with detergent/proteinase solutions and exposing the washed instruments to 6 M urea or 4 M guanidinium thiocyanate, which have shown moderate to good disinfection of BSE in tissue extracts.[46](See **73. Creutzfeldt-Jakob Disease and Other Prion Diseases**.)

MYCOTIC ANEURYSM

Dr. William Osler coined the term *mycotic aneurysm*in 1885. Mycotic cerebral aneurysms are localized dilatations of intracerebral arteries due to infection of the vessel wall. The term *mycotic*erroneously may imply fungal infection, but almost any microorganism may cause these *infectious aneurysms*. Septic emboli to a cerebral vessel wall may produce focal septic arteritis, which can lead to local vessel dilatation and rupture, with resulting intracerebral hemorrhage. Some believe that hematogenous microbial seeding of a previously damaged atherosclerotic vessel is the most common mechanism, and that this accounts for the 3:1 male predominance.[53]Mycotic aneurysms may be shown to result from septic microembolization to the vasa vasorum of intracranial arteries.[54]However, the small peripheral intracranial arteries that are frequently involved are devoid of vasa vasorum, and direct bacterial penetration of the arterial wall is an alternative mechanism. Intracranial or somatic mycotic aneurysms occur as rare complications of *S. aureus*infectious endocarditis, but they may also complicate endocarditis caused by streptococci, other bacteria, or fungi (e.g., *Candida*spp.).

Mycotic aneurysm rupture tends to occur early in the course of a patient's systemic infection. Ruptured mycotic aneurysms comprise only a small percentage of all intracranial aneurysms. Most cerebral mycotic aneurysms present clinically as a sudden, often fatal, subarachnoid or intracerebral hemorrhage. Before rupture, premonitory signs or symptoms include seizures, ischemic deficits (stroke), or cranial nerve abnormalities. Rupture may occur even after the patient has been started on appropriate antibiotics, sometimes even after therapy has been completed. Some aneurysms may leak slowly before rupture, producing symptoms of meningeal irritation. When rupture occurs, it usually causes either subarachnoid or intracranial hemorrhage, but subdural hematomas have been described. Also described, though rarely, are asymptomatic mycotic aneurysms that resolve with antibiotic therapy.

Especially problematic are mycotic aneurysms resulting from prosthetic valve endocarditis in patients receiving full anticoagulation.[55]The diagnosis of mycotic aneurysm has reflected the evolution of angiographic methodology. Magnetic resonance angiography represents a recent advance in detection of cerebral aneurysms. If hemorrhage has occurred, conventional cerebral angiography is still the method of choice.

Optimal management of intracerebral mycotic aneurysms should include medical and surgical collaboration. Appropriate antibiotic therapy should be initiated as soon as possible using the guidelines for treatment of infectious endocarditis.[56]The distal location of most intracerebral mycotic aneurysms

associated with infectious endocarditis permits ligation and excision with fewer complications compared with surgery for berry aneurysms in or near the circle of Willis. Serial angiographic studies may be useful because aneurysms may change in size or new lesions may develop. Surgery is indicated for aneurysms that are increasing in size. It has also been recommended that for aneurysms related to infectious endocarditis, the duration of antibiotic therapy be extended to 6 to 8 weeks even if the organism is highly susceptible and the aneurysm has been resected surgically. However, the natural history of an intracerebral mycotic aneurysm is unpredictable, and therapy must be individualized, especially in patients with multiple lesions. Some aneurysms may regress and resolve on antibiotic therapy, whereas others may enlarge.

The American Heart Association has reviewed the topic of mycotic aneurysms secondary to bacterial endocarditis.[57]The mortality rate of recognized mycotic aneurysm may be as high as 80 percent for aneurysms that have ruptured and 30 percent if the aneurysm is intact. However, most published case descriptions do not specify the reasons for choosing a particular therapeutic approach. Differences in outcome may relate to the patient's clinical condition at the time of diagnosis and to the size and location of the mycotic aneurysm.

INFECTION PREVENTION AND ISOLATION IMPLICATIONS

For most of the CNS infections described, Standard Precautions effectively limit the transmission of these infections because they are not efficiently spread person to person. However, empiric use of Transmission-based Precautions, specifically Airborne or Droplet Precautions, may be indicated in some situations until diagnosis is confirmed (see **29. Isolation Precautions (Transmission-based Precautions)**). For suspected meningitis cases, it is essential to recognize (and exclude when possible) acute bacterial meningitis, especially meningococcus (and to a lesser extent *H. influenzae*, now a rare condition since the widespread requirements for vaccination), as soon as possible. This is because of the need for providing isolation, reporting to state/local health departments, providing prophylaxis to close contacts (including assessing who fits into this narrow defined group), and allaying fear. Clinician impression and laboratory testing of CSF, including Gram stain and white blood cell count with differential, can provide clues to preliminary diagnosis.

Iatrogenic introduction of CNS infections due to breaches in infection control techniques remains a threat to patients. An article published in January 2010 in the *Morbidity and Mortality Weekly Report*describes two clusters of meningitis among five otherwise healthy women who received spinal anesthesia during labor and subsequently developed clinical meningitis. Four cases were confirmed to be caused by *Streptococcus salivarius*, a bacterium of the normal oral flora which was likely transmitted via the administering anesthesiologist and/or contaminated equipment as it was not necessarily a common practice to wear masks while performing bedside spinal procedures for one of the sites where this epidemic was found.[58]

More recently, the *New England Journal of Medicine*described in December 2012 an outbreak of fungal meningitis in otherwise immunocompetent patients who received epidural or paraspinal glucocorticoid injections contaminated with environmental molds from a single compounding pharmacy in New England. Due to rapid recognition of the outbreak by an astute clinician, and subsequent cooperation by local, state, and federal public health officials, high-risk patients were quickly identified and notified of their exposure. This led to rapid prompt evaluation and initiation of therapy, which were essential in preventing more severe sequelae of the disease.[59]

Both examples underscore the importance of strict infection control practices in the prevention of infection, particularly CNS infections.[58,59] In addition, the cooperation between infection preventionists and the state and local health departments cannot be underestimated. Infection preventionists are often the liaisons to state and local health departments for reporting, follow-up on potential clusters of disease, and other requests (including additional laboratory testing, e.g., viral encephalitis). They are likely to be involved in such activities as setting policy for care of ventricular shunts, postexposure prophylaxis, and sterilization/disinfection issues, such as those for suspected/confirmed CJD cases. Infection preventionists should collaborate with the surgical team to track and monitor any postsurgical infections involving the CSF and to track any progression of infection to the CSF in neonates and other hospitalized patients.

Conclusions

CNS infection may be caused by a variety of agents and manifest with different symptoms and disease processes. Many infections are successfully managed with pharmacological or surgical intervention, some are self-limiting, and a few are untreatable.

International Perspective

CNS infections are common throughout the world in industrialized countries and in developing and resource-poor settings. The critical difference is that in the developing and resource-poor countries, access to care, medications, vaccinations, and sanitary conditions is extremely limited at best. The population in these settings often faces unsanitary conditions and poor nutrition, which also contributes to exposure to some agents and a poor response against infection when it does occur.

Berkhout[60] reports on the first worldwide conference, 2008 Infectious Diseases of the Nervous System: Pathogenesis and World Impact on Neuroinfection, which was held at the Pasteur Institute of Paris. The developed world actively studies and researches better management of viral encephalitis and bacterial meningitis. However, there is much less attention focused on the often fatal nervous system infections caused by neurotropic viruses, parasites, and mycobacteria in tropical regions and underdeveloped countries. The gathering promoted worldwide interactions among scientists and presented the latest research results on these neurotropic pathogens. Policymakers, medical teams, scientists, and pharmaceutical companies are challenged to create systems in developing countries for sharing of care with access to vaccines for prevention and drugs for treatment of these life-altering neurotropic pathogens: HIV alone and in combination with other infectious agents, tickborne encephalitis, rabies and rabies-related lyssaviruses, cryptococcal meningitis, *S. pneumoniae, H. influenzae*, and *N. meningitides*.[60,61,62,63,64]

Abstract

Enterobacteriaceae are a large, diverse group of facultative Gram-negative rods, recovered as natural inhabitants of the environment and the large intestines of humans and animals. They are important pathogens in healthcare- and community-associated infections in the United States and worldwide. The spectrum of infections includes bacteremias, pneumonias, surgical site infections, and urinary tract infections. Patients at greatest risk include those in medical and surgical intensive care units and residents of short- and long-term acute care hospitals. Infants, the elderly, the immunocompromised, and those with extensive exposure to healthcare are the most vulnerable. In developing countries they are among the leading cause of diarrheal disease and death of children under age 5. Increasing antibiotic resistance to third-generation cephalosporins, fluoroquinolones, and carbapenems results in diminished treatment choices for the prevention and management of both healthcare- and community-associated infections. Several members of this group may also be used to launch biological weapons. Strategies for prevention include healthcare personnel education and training, checklists, surveillance, and zero tolerance for noncompliance with evidence-based best practices. Adoption and monitoring of patient and quality improvement outcomes are essential to reducing infections and developing a culture of patient safety.

Key Concepts

• Enterobacteriaceae are among the most common, life threatening, and preventable healthcare-associated infections (e.g., bacteremia, pneumonias, and surgical site infections).

• They are important pathogens in common community-associated infections (urinary tract infections, diarrheal diseases, lower respiratory tract infections).

• Members include Gram-negative, short, coccobacillary, or straight, non-spore-forming bacilli that grow well in the presence or absence of oxygen (facultative).

• Members of this group are normal inhabitants of the gastrointestinal tract of humans, cattle, other mammals, reptiles, and fowl. They are also recovered worldwide from soil, plants, sewage, aquatic environments, improperly prepared food, and contaminated water and medical equipment.

• Members of this family are often recovered as transient residents on hands of healthcare personnel and are frequent colonizers of patients with extended hospital stays or treatment with broad-spectrum antibiotics.

• Virulence factors include: toxins, adhesions, hemolysins, plasmids, fimbriae, pili, enzymes, mobile genetic elements, and biofilm production. Members initiate both overt and opportunistic infections in humans.

• All grow well on routine laboratory media. Molecular methods and biochemical profiles (via kits or automated systems) are used to identify members in as early as 2 hours. Serology and, additionally, molecular techniques are used to characterize specific serotypes (e.g., *Escherichia coli*O157:H7) or clones associated with diarrheal diseases and outbreaks.

• Patients at greatest risk for healthcare-associated infections include infants; children; the elderly; debilitated, immunocompromised patients; patients with catheters or other indwelling medical devices; those in intensive care units, on broad-spectrum antibiotics, in long-term care, or on dialysis; or those with extended hospital stay. Populations in crowded areas or areas with poor sanitation are at greater risk for gastrointestinal infections.

• Treatment outcomes with third-generation cephalosporins are no longer predictable.

• Increasing recovery of extended-spectrum beta-lactamase-producing and other multidrug-resistant members dictate in vitro susceptibility testing and knowledge of local antibiograms.

• The emergence of carbapenemase-producing Enterobacteriaceae is a mounting public health concern. Carbapenemase enzymes have broad spectrum hydrolyzing activity, thereby rendering all penicillins, cephalosporins, and carbapenems ineffective. They are often located on mobile genetic elements with other resistant genes which results in multidrug or "pan"-resistant members with limited or no therapeutic options.

• The majority of Enterobacteriaceae species in the United States remain susceptible to the fluoroquinolones, amikacin, and imipenem. New options for multidrug- or pan-resistant isolates include colistin, polymyxins, and tigecycline.

• Strict adherence to evidence-based "best practices" (hand washing, use of alcohol-based hand rub, barrier protection, proper maintenance of equipment and the environment, healthcare personnel and consumer education) are required to prevent and control these infections.

• Several members in this group may be used as biological weapons (*Yersinia pestis, Salmonella*species*, Shigella, and Escherichia coli*).

Importance To Infection Prevention And Control

Enterobacteriaceae may account for 80 percent of clinically significant isolates of Gram-negative bacilli and 50 percent of clinically significant bacteria recovered in clinical microbiology laboratories. They are also the etiologic agents in nearly one-third (30 to 35 percent) of all septicemia cases, more than 80 percent of urinary tract infections, and a significant percentage of pneumonia and intestinal infections.[1,2]

They are also important agents in myriad other preventable healthcare- and community-associated infections. These include skin and soft tissue, osteomyelitis, septic arthritis, ocular infections, intraabdominal abscesses, and wound and lower respiratory site infections.[1,2,3,4,5,6]More importantly,

healthcare-associated infections (HAIs) associated with the Enterobacteriaceae are among the most life threatening, preventable, and costly infections encountered in healthcare facilities. Implementation and adherence to evidence-based best practices for the prevention, surveillance, and control of these preventable infections across the continuum of care will reduce their contributions to HAIs as well as improve patient safety. The single most important means to effectively reduce the transmission and horizontal spread of Enterobacteriaceae and other microorganisms in all healthcare settings is compliance with proper hand washing. Compliance with hand washing and other basic tenets of infection prevention (aseptic technique, education, and surveillance) is important to reduce the risk of colonization and infection. Surveillance programs should be implemented and maintained to monitor epidemiology, emerging resistance, shifting pathogen trends, and to detect outbreaks, direct therapy, and guide quality improvement and patient outcomes.[7,8,9]

Implementation of Standard Precautions and aggressive infection control and prevention practices in all healthcare settings is also warranted to reduce transmission of microorganisms from person to person, for both recognized and unrecognized reservoirs. Transmission-based Precautions may be required for patients with infectious diarrhea or other enteric pathogens that are highly transmissible or of epidemiological importance (e.g., bioterrorism agent, carbapenemase-producing [CPE], and other multidrug-resistant isolates).[10]

Adopting the strategies and recommendations in the Compendium of Strategies to Prevent Healthcare-Associated Infections in Acute Care Hospitals provided by the combined Society for Healthcare Epidemiology of America (SHEA) and the Infectious Disease Society of Standards and Practice Guideline Committee taskforce along with the new Centers for Disease Control and Prevention (CDC) guidelines for detection and prevention of carbapenem-resistant Enterobacteriaceae (CRE) should be routinely implemented to detect and protect patients from infections with this group of organisms.[11,12,13,14]

Background

The purpose of this chapter is to provide a brief overview of the epidemiology and pathogenesis of the family Enterobacteriaceae and to highlight strategies to prevent and reduce infections and other adverse patient outcomes associated with members of this group.

The Enterobacteriaceae are a large, diverse family of small, Gram-negative, coccobacillary, or straight rods. They inhabit a wide variety of niches, including soil, plants, water, and gastrointestinal tracts of humans and animals. Because of their natural affinity for the gastrointestinal tract, members are often referred to as "enterics" or coliforms. The majority of the species is morphologically indistinguishable and shares similar biochemical and physiological features. All are oxidase negative, ferment glucose,

reduce nitrate, and grow equally as well in air (aerobic) or without air (anaerobic). All but three genera are motile. Enterics are the most frequent group of Gram-negative rods encountered in the microbiology laboratory and among the most common causing community- and healthcare-associated infections. Currently there are more than 30 genera and 120 species in the family Enterobacteriaceae. Taxonomic and molecular characterizations keep this list is in a constant change of flux and expansion.[1,2,3,4'15]

However, 95 percent of those associated with human disease or colonization are restricted to as few as 10 genera and 20 to 25 species. The most familiar species recovered from extraintestinal disease are *Escherichia coli*, *Enterobacter cloacae*, *Klebsiella pneumoniae, Serratia marcescens,*and *Proteus mirabilis. Salmonella*species, *Shigella*species, and *E. coli*are common agents of gastroenteritis and colitis (see Tables 75-1 and 75-2).[1,2,3,4'15]

Basic Principles

PATHOGENESIS

A variety of specific and nonspecific virulence factors interact to initiate colonization or establish disease. Common to all members is the complex antigenic structure of the cell wall and outer surface appendages. The O or somatic antigen is a heat-stable lipopolysaccharide composed of three components: (1) an antigenic variable O polysaccharide (unique to species), (2) a core polysaccharide (common to all species), and (3) lipid A. Endotoxin activity is coupled with the lipid A portion. Lipid A is released during growth, cell death, or lysis. Many of the adverse systemic manifestations (fever, shock, disseminated intravascular coagulation [DIC]) of Gram-negative infections are due to endotoxin (lipid A). K, or capsular, antigens are made of either proteins or polysaccharides. The capsule or "slime layer" protects encapsulated strains from phagocytosis and serum killing. Capsular antigens on *Salmonella*species are classified as Vi antigens and play an important role in disease. H or flagellar antigens are located on flagella and are constructed of proteins. These appendages confer motility and, along with pili, facilitate attachment[1,2,3,4,5'15](Table 75-3).

Table 75-1 Extraintestinal Infections Associated with Common Enterobacteriaceae

Organisms	Clinical Syndrome(s)	Mechanisms	Risk Factor(s)	Infection Prevention Issues	Laboratory Identification/Tests

Escherichia coli	UTI, most common, pyelonephritis, cystitis	Adherence to urinary tract epithelium cells with Type P, Type 1 fimbriae (uropathogenic strains). Organisms are seeded from the gastrointestinal tract with specific serotypes (e.g., O4, O6, O75 are frequent serotypes).	Community-sexually active females, others (short urethra, colonization of vagina, closeness of anus) Health-care related: catheterization, prolonged institutional stay, underlying disease (diabetes, cancer, etc), obstruction of urinary flow.	Limit catheterization and LOS in healthcare facilities; use silver-impregnated catheters. Perform targeted surveillance in high risk areas. Practice aseptic technique, use gloves, and wash hands between patients. Use closed drainage system. Maintenance of unobstructed urine flow. Education of healthcare providers on the proper care and insertion of catheters.	Culture and quantitation of clean catch or catheterized urine.
	Pneumonia, bronchitis (LRTI)	Colonization of lower respiratory tract. Aspiration of contaminated respiratory secretions	Community-rare, underlying disease-diabetes, COPD, alcoholism Health-care related: immunosuppressed or debilitated, ventilator-dependent patients, presence of gastric intubation, endotracheal tube, supine position, ICU patients at greater risk. Increased fibronectin degrading protease in saliva.	Colonization vs infection. Difficulty in establishing actual infection, quantitative cultures. Reduction of oropharyngeal and gastric colonization and aspiration in ventilator-dependent patients. Reprocessing, staffing issues.	Specimen of choice in descending order: BAL > PSB > PCA > EA > sputum

	Bacteremia	Organisms may enter the bloodstream from a focus of infection of the urinary or the gastrointestinal tracts. Strains with S-fimbrial antigens associated with neonatal sepsis.	Community-age, malnutrition, trauma, underlying disease Health-care related: colonization, admission to ICU comorbidities, UTI, presence of catheter, invasive procedures. Cross contamination (hands of HCP).	As for UTI, maintenance and care of IV or other catheter. Adherence to strict infection prevention protocols, especially hand washing. Establishment of a needless and alcohol-based system for caregivers. Contaminated fomites and solutions.	Adequate number, volume, and timing of blood cultures
	Wound, surgical site infections	Organisms are usually endogenous or acquired from the environment, usually at the time of surgery.	Mainly-Health-care related: Hair removal. Duration and type of surgery. Underlying disease. Trauma including burns, surgery, accidents. Older patients are more susceptible to wound infections (declining immunity)	Cross contamination, duration of surgery, preoperative antibiotics. Use of corticosteroids. Surgeon specific surveillance and feedback.	Use aseptic technique to collect pus, tissue of drainage. Prompt delivery to microbiology. Evaluation for presence of organisms (stains and culture) and resistant isolates (sensitivity)
	Neonatal meningitis	Colonization of the gastrointestinal tract at the time of delivery from colonized birth canal; 75 percent of cases are associated with K1 capsular antigen or strains with S fimbriae	Infants in their first month of life.	Management with antibiotic therapy. Cross contamination (hands of HCP, equipment)	CSF culture and sensitive. Gram stain of CSF may reveal the organisms.
	Central nervous system Infections (adults)	Neurosurgical patients, neonates, and procedures that penetrate the CNS	Hospital patients undergoing surgery of the CNS.	Management with antibiotic therapy.	CSF culture and sensitive. Gram stain of CSF may reveal the organisms.

Klebsiella pneumoniae	Necrotizing lobal pneumonia. "Currant jelly" appearance of sputum (lung necrosis and blood). Bronchitis and bronchopneumonias (less severe presentation)	Presence of capsular aids in adherence to respiratory mucosa. Types 1, 3. *Klebsiella*may be a commensal on skin, in the nasopharynx, and GI tract and infections are endogenous.	Community: alcoholics, individuals with compromised pulmonary function, severe underlying disease.	Management with antibiotic therapy. Cross contamination (hands of HCP, equipment).	Sputum with "currant jelly" appearance. A positive sputum must be supported by clinical signs (fever, presence of WBC on Gram stain and signs of system inflammation). Detection of carbapenemase producing strain may be missed with current automated systems.
	Healthcare-associated pneumonia	Colonization of lower respiratory tract. Aspiration of contaminated respiratory secretions.	Health-care related: immunosuppressed or debilitated, ventilator-dependent patients, presence of gastric intubation, endotracheal tube, supine position, ICU patients at greater risk. Increased fibronectin degrading protease in saliva.	Colonization vs Infection. Difficulty in establishing actual infection, quantitative cultures. Reduction of oropharyngeal and gastric colonization and aspiration in ventilator dependent patients. Reprocessing, staffing issues.	Specimen of choice in descending order: BAL > PSB > PCA > EA > sputum
	Neonatal meningitis, meningitidis	Colonization and invasion of bloodstream.	Premature and underweight infants. Presence of medical device.	Colonization of GI tract with GNI. Cross contamination (hands of HCP).	CSF culture and sensitive. Gram stain of CSF may reveal the organisms.
	UTIs	Adherence to urinary tract epithelium cells with Type 1 fimbriae (uropathogenic strains). Organisms are seeded from the gastrointestinal tract with specific serotypes (e.g., O4, O6, O75 are frequent serotypes).	Community-rare Health-care-related: catheterization, prolonged institutional stay, underlying disease (diabetes, cancer, etc), obstruction of urinary flow.	Same as for *E. coli*	Culture and quantitation of clean catch or catheterized urine.

	Wound, surgical site infections	Organisms are usually endogenous or acquired from the environment—usually at the time of surgery.	Mainly-Health-care related: Hair removal. Duration and type of surgery. Underlying disease. Trauma including burns, surgery, accidents. Older patients are more susceptible to wound infections (declining immunity).	Cross contamination, duration of surgery, preoperative antibiotics. Use of corticosteroids. Surgeon-specific surveillance and feedback.	Use aseptic technique to collect pus, tissue of drainage. Prompt delivery to microbiology. Evaluation for presence of organisms (stains and culture) and resistant isolates (sensitivity).
Enterobacter cloacae	Healthcare-associated pneumonia, UTI, sepsis, neonatal meningitis, surgical wound infections	Opportunistic pathogens, colonization and adherence to tissues, transmission on hands of HCP, exposure to contamination of food, solutions, and medical equipment. Reduction of normal or resident flora by exposure to broad-spectrum antibiotics.	Health-care related: immunosuppressed or debilitated, ventilator-dependent patients, presence of gastric intubation, endotracheal tube, supine position, ICU patients at greater risk. Increased fibronectin degrading protease in saliva. Presence of indwelling medical devices, IV, catheters, etc. Cross contamination (hands of HCP). Broad-spectrum antibiotics.	Same as for *E. coli*	Same as for *E. coli*
Serratia marcescens	Surgical wound infections, bacteremias, UTI, LRTI, and bacteremias	Opportunistic pathogens, colonization, transmission, hands of HCP, contamination of food, infusion fluids, and enteral feeds.	Same as for *E. coli*	Same as for *E. coli*	Appropriate specimens from infected organ system or site. May include blood, urine, pus, sputum, tissue, CSF, or other.
Citrobacter species	Neonatal meningitis, UTI, respiratory infections	Opportunistic pathogen	Infants <2 (meningitis), same as for *E. coli*	Same as for *E. coli*	Same as for *E. coli*
Proteus species	UTI, kidney stones, pyelonephritis, renal abscess	Organisms hydrolyze urea, form a type of kidney stone, block the flow of urine, opportunistic pathogen	Indwelling Foley catheter. Prolonged long stay in healthcare facility.	Same as for *E. coli*	Culture

	Pneumonia, surgical, wound infections	Destructive ear infection, septicemia	Same as for *E. coli*	Same as for *E. coli*	Appropriate specimens from infected organ system or site.
Morganella species	UTI, surgical wound infections, and respiratory infections	Opportunistic pathogen	Same as for *E. coli*	Same as for *E. coli*	Appropriate specimens from infected organs system or site
Providencia species	UTI, surgical wound infections	Opportunistic pathogen	Same as for *E. coli*	Same as for *E. coli*	Appropriate specimens from infected organs system or site

BAL, bronchoalveolar lavage; CSF, cerebrospinal fluid; CNS, central nervous system; COPD, chronic obstructive pulmonary disease; GI, gastrointestinal; HCP, healthcare personnel; ICU, intensive care unit; LOS, Length of Stay; PCA, protected catheter aspirate; PSB, protected specimen brush; UTI, urinary tract infection; WBCs, white blood cells.

Table 75-2 Enteric Infections Associated With Common Enterobacteriaceae

Organisms	Clinical Syndrome	Mechanism(s)	Common Source(s)	Risk Group(s)
Escherichia coli(EHEC) enterohemorrhagic	Hemorrhagic colitis-characterized by severe cramping, watery diarrhea that becomes grossly bloody. Complications: Hemolytic uremic syndrome (HUS), thrombotic thrombocytopenic purpura (TTP)	Production of potent verotoxin, Shiga-like toxins that damage the lining of the intestines. These are similar or identical to the toxin produced by *Shigella*dysenteriae. Disease is associated with certain serotypes. Ex: *E. coli*O157:H7, O26:H11, O111:H8, O103:H2	Uncooked or raw hamburger, milk, apple cider. Person to person in day care and nursing homes.	Children (<5) and the elderly at greatest risk. Young (HUS), elderly (TTP)

Escherichia coli(ETEC) enterotoxigenic	Gastroenteritis, traveler's diarrhea-watery diarrhea, nausea, abdominal cramps, self-limiting	Colonization of the small intestines, proliferation and toxin production, heat stable and/or heat labile enterotoxins-leakage of electrolytes	Food or water contaminated with human sewage or animal feces. Infected food handlers. Poor sanitation.	Travelers to foreign countries
Escherichia coli(EPEC) enteropathogenic	Infantile diarrhea-watery or bloody diarrhea, may be prolonged and lead to dehydration, electrolyte imbalance, and death	Organisms adhere to and damage the small intestines by production of a cell associated verotoxin, which is mediated by a plasmid. Other virulence factors include bundle forming pili and intimin. Serotypes: O18:H7, O44:H3, 020:H2	Contaminated beef, chicken, and infant formula. Contaminated water.	Infants that are bottle fed: reconstitution of formula with contaminated water
Escherichia coli(EIEC) enteroinvasive	Bacillary dysentery-characterized by a mild diarrhea with mucus and blood in the stool. Abdominal cramps, fever, chills, and generalized malaise. Complications: HUS (pediatric cases)	Low infectious dose-organisms possess plasmids which mediated the invasion and destruction of epithelial cells of the colon.	Contaminated beef, chicken, and infant formula. Contaminated water.	Infants and children in emerging nations
Escherichia coli(EAEC) enteroaggressive	Acute and chronic diarrhea—watery diarrhea, vomiting	Enteroaggressive heat stable enterotoxin (EAST1)	Contaminated food or water	All age groups
Escherichia coli(DHEC) diffusely adherent	Infantile diarrhea—watery or bloody diarrhea, may be prolonged and lead to dehydration, electrolyte imbalance, and death	Alpha hemolysin and cytotoxic necrotizing factor 1	Contaminated food or water	Infants in emerging nations
Escherichia coli	Necrotizing enterocolitis	Multifactorial	NICU	Infants with low birth weight, low gestational age, low Apgar score, perinatal complications, hyaline membrane disease, and umbilical catheterization

*Salmonella*serotype Typhi	Typhoid, enteric revers, febrile illness, intermittent fever with headache, malaise, and anorexia. Bacteremia, asymptomatic carriage (gallbladder).	Infectious dose = HIGH (1,000,000 organisms). 10–14 days incubation: Heat stable and labile enterotoxins similar to those of *Shigella*and *E. coli*. Organisms attach, penetrate, and invade the mucosa of enterocytes in the small intestine. Mucosal infection progresses to hemorrhage and ulceration and sometimes perforation. Vi-capsular antigen is important. Transmission is via fecal-oral route.	Contaminated food or water, duodenal intubation	All age groups, international travelers, laboratory workers, HIV patients
*Salmonella*serotype Enteritidis	Gastroenteritis, nausea, vomiting, nonbloody diarrhea, fever, abdominal cramps, myalgias, and headache. Spontaneous resolution. Bacteremia.	Infectious dose = HIGH (100,000,000), 6–48 hours after ingestion of contaminated food. Enterotoxins locally invade the epithelial cells of the gut, then migrate to the lamina propria layer where they multiply and stimulate active fluid secretion.	Contaminated food. Luncheon food, precooked roast beef, cold cuts. Dairy products.	Most common isolate in the U.S. All age groups, HIV patients (bacteremia), laboratory workers
*Salmonella*serotype Typhimurium	Gastroenteritis, bacteremia as above	As above	Contaminated food or water. Eggs, Fiberoptic endoscope, clover sprouts, milk, ice cream, raw ground beef.	Elderly, infants, immunocompromised
*Salmonella*Serotype, others	Gastroenteritis, bacteremia as above	As above	Contaminated food or water, rectal thermometer, rubber tubing, alfalfa sprouts	All age groups, HIV patients
S. dysenteriae(serogroup A)	Bacillary dysentery: characterized by a mild diarrhea with mucus and blood in the stool. Abdominal cramps, fever, chills, and generalized malaise. Complications: HUS (pediatric cases)	Infectious dose is LOW (100 to 200 organisms). Shiga toxin is two-stage disease. First ingestion: noninvasive colonization, production of enterotoxin; watery diarrhea; blocks uptake of glucose and electrolytes. Second: adherence and invasion of large intestines, increased cytotoxic activity; inhibits protein synthesis causing cell death and damage to the large intestines.	Contaminated food and water. Person-to-person (fecal-oral) transmission.	Mainly a pediatric disease, common in emerging nations
S. flexneri(serogroup B)	Bacillary dysentery; most common in emerging nations	As above	Contaminated food and water. Person-to-person (fecal-oral) transmission.	Mainly a pediatric disease; common in emerging nations
S. boydii(serogroup C)	Bacillary dysentery	As above	Contaminated food and water. Person-to-person (fecal-oral) transmission.	

S. sonnei(serogroup D)	Bacillary dysentery; most common cause in the United States	As above	Men who have sex with men, day care and mental institutions, unchlorinated wading pool. Contaminated food or water (person-to-person outbreaks = largest).	Children in child care, institutionalized populations (prisons, mental institutions). Native Americans, orthodox Jews, and international travelers
K. pneumoniae	Enteritis, colitis, necrotizing enterocolitis	Heat stable and heat-labile enterotoxin	NA	Children under 3 in emerging/developing countries
*Enterobacter*species	Necrotizing enterocolitis	Heat stable and heat-labile enterotoxin	NICU	Children under 3 in emerging/developing countries
Citrobacter freundii	Infantile diarrhea (rare), enteritis, colitis	Verotoxin, antigen 0157	NA	Infants
Yersinia	Bloody diarrhea			
	Enterocolitis	Enterotoxin	Unpasteurized milk, contaminated water, raw, undercooked pork	Young children, males, adults

Serological classification is based on the presence and detection of the O, K, and H antigens. Differential combinations of these antigens within and between species allow for great antigenic diversity and gradient of pathogenicity. There are at least 150 O, 100 K, and 50 H serotypes. Specific serotypes are linked with specific disease syndromes (i.e., *Escherichiacoli*O157:H7).[1,2,3,4,5,15,16]

The tendency to grow as microcolonies surrounded by a complex organic matrix or *biofilm*on surfaces, medical devices, and within living and dead tissues protects members from the deleterious effects of antibiotics, toxic substances, and serum killing. Inside this matrix of extracellular polymers, organisms are highly resistant to antibiotics, immune clearance, and eradication. This mode of growth may be implicated in up to 60 percent of persistent and chronic HAIs. Documented biofilm-associated enteric infections include biliary tract infection, bacterial prostatitis, intensive care unit (ICU) pneumonia, urinary catheter cystitis, and biliary stent blockage.[17,18]

EPIDEMIOLOGY

Enterobacteriaceae rarely infect patients that are immunocompetent. Host defenses must be breached for disease to occur. The skin or mucous membranes may be breached by trauma, surgery, catheterization, tracheal intubation, or antibiotic therapy. Opportunistic organisms or pathogens may gain entry through third-degree burns, ulcers, intravenous catheters, surgical or instrumental manipulation, or contaminated food and beverages.[1,2,4,5,7,11,16,19,20]

Common vehicles associated with outbreaks include contaminated IVs, enteral feeding and saline solutions, disinfectants, electrocardiogram bulbs, powered infant formulas, urinals, and blood culture equipment. Medical interventions such as corticosteroid administration, radiotherapy, and other immunosuppressive therapy also contribute to the risk of infection. Cancer- or drug-induced neutropenia is also an important predisposing factor in bacteremia.[1,2,4,5,7,11,1]

Table 75-3 Virulent Factors Associated With the Enterobacteriaceae

TYPE	Factor	Mechanisms of Action
Structure	Cell wall (LPS-polysaccharides and lipid A) endotoxin	Common to all aerobic and some anaerobic, Gram-negative bacteria, released upon death. Activates macrophages, white blood cells, releases cytotoxins, causes "septic shock," necrosis, DIC, and death.
	Somatic O antigens	Confirms specific serotype. Serotypes are associated with specific syndromes.
	Flagellar H antigens	Facilitates motility and adherence to gastrointestinal, urinary epithelial cells. Also assists in invasion of mucosa.
	Capsule, K antigens	Prevents phagocytosis, evades immune mechanisms.
	Pili, fimbriae	Facilitates adherence and invasion of mucosa and epithelial cells, first step in colonization.
	"Pathogenic islands"	Provides resistance to antibiotics, production of toxins, hemolysins; may be chromosomal or plasmid mediated.
Toxins	Endotoxins	Cells wall, mainly Lipid A (see structure)
	Exotoxins (Enterotoxins)	Heat-labile elevates cAMP, with altered electrolyte transport and excessive fluid secretion, cell destruction, short range, tissue specificity.
		Heat-stabile elevates cyclic GMP, increases secretion of fluids from small intestines.
		Shiga-like toxin: excessive tissue destruction
	Neurotoxins	Targets central nervous system, inhibits protein synthesis, resulting in headaches, meningeal symptoms and seizures (*S. dysenteriae*).
	Hemolysins (cytotoxins-membrane bound)	Lysis of red and white blood cells, uremic syndrome, long range, targets many cells and tissues.
Plasmids	Colonization factors, hemolysins, antibiotic drug resistance (R), toxins	Assists in adherence to epithelial cells, causes cell destruction, provides protection against antibiotics.

The normal gastrointestinal flora in small numbers is important in preventing disease through bacterial competition. Disruption of the normal intestinal flora by antibiotic therapy, instrumentation, or surgery compromises this defense mechanism and may allow "enterics" to colonize or overgrow. Increased hospital stays and exposure to broad-spectrum antibiotics increase the chance of colonization with the Enterobacteriaceae. Prolonged antimicrobial therapy may "select" and lead to the emergence of multidrug-resistant organisms that result in longer stay, added medical intervention, and/or death.

Increased production of salivary protease, which leads to degradation of fibronectin and exposed binding sites for Gram-negative rods, is a risk factor for patients in long-term care facilities or with an extended ICU stay. In general, the very young, very old, immunocompromised, or debilitated are at greatest risk for HAIs. Those exposed to contaminated food and water are at greatest risk for common community-associated enteric infections.

Enterobacteriaceae are spread in healthcare settings from person to person via the hands of healthcare personnel or from environmental fomites and reservoirs such as mechanical devices, environmental foci, or contaminated solutions. Community reservoirs usually include contaminated food and water. Establishment of disease is multifaceted and involves a combination and interaction of factors that are host, pathogen, medical intervention, and environment specific.[1,2,3,4,5]

CLINICAL SYNDROMES

Although declining, members of the Enterobacteriaceae remain important pathogens in the four most common device- and procedure-related infections in acute care facilities (Figure 75-1). They are among the top 10 pathogens recovered from patients in U.S. ICUs, with infections ranging from 19.6 percent of central line-associated bloodstream infections (CLABSIs) to 47.9 percent of catheter-associated urinary tract infections (CAUTIs), according to results reported in the 2009 to 2010 National Healthcare Safety Network (NHSN) survey (Figures 75-2, and 75-3). Members also ranked in the top 10 pathogens recovered from ventilator-associated pneumonia (VAP; 30.6 percent) and surgical site infections (SSIs; 22.4 percent). *E. coli*(39.9 percent, *n*= 9,351) was the most frequently recovered Enterobacteriaceae, followed by *Klebsiella*species (pneumonia, oxytoca; 27.6 percent, *n*= 6,470), *Enterobacter*species (16.3 percent, *n*= 3,821), *Proteus*species (8.7 percent, *n*= 2,031), and *Serratia*species (7.4 percent, *n*= 1,737) (Figure 75-3).[21,22]

Blood Infections (Bacteremia, Septicemia)

Bloodstream infections (BSIs) or bacteremias caused by the Enterobacteriaceae are usually a result of contiguous spread from the urinary tract, lungs, or gastrointestinal tract. Other portals of entry include surgical sites, decubiti, and central venous lines. These are life-threatening infections due in part to the systemic effects of endotoxins (fever, shock, thrombocytopenia, activation of complement, DIC, and decreased peripheral circulation) and in part to the difficulty of managing frequent multidrug-resistant isolates.[23]

There has been a 69 percent decline in the percentage of Enterobacteriaceae recovered as bloodstream pathogens in National Nosocomial Infections Surveillance (NNIS) hospitals since the early 1980s. In the latest data from NHSN (2009 to 2010), they accounted for 19.6 percent. This was a 58

percent increase in the percentage of Enterobacteriaceae reported for the NHSN 2006 to 2007 baseline data. Frequent isolates, in descending order, were *Klebsiella*species (7.9 percent, *n*= 2,407), of *Enterobacter*species (4.5 percent, *n*= 1,365), *E. coli*(4.0 percent, *n*= 1,206), *Serratia*species (2.5 percent, *n*= 762), and *Proteus*species (0.8 percent, *n*= 232). The first three members were among the top 10 pathogens recorded from CLBSIs with ranks of 5, 8, and 9, respectively.[21,22,24,25]

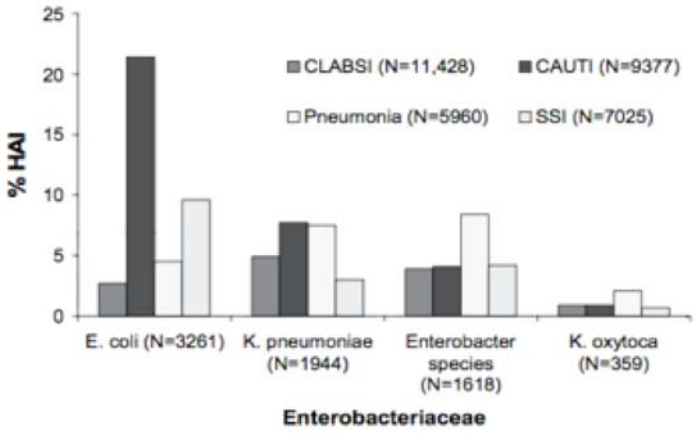

Figure 75-3.

Pathogen distribution of Enterobacteriaceae: NHSN January 2005 to October

View Image

Although, patient populations in acute care ICUs are at an increased risk for CLABSIs, recent data document the increasing risks in patient populations outside the ICU. This is associated with the increasing number of central lines in these areas. Frequent independent risk factors are microbial colonization of the catheter hub and insertion site, femoral and/or jugular catheterization, prior extended hospital stay, and prolonged catheterization.[23,26]

Education of personnel in the insertion and care of the central lines, performance of a CLABSI risk assessment, proper maintenance of central lines, and appropriate antibiotic therapy are recommendations that may help reduce healthcare-associated BSIs.[23,26]

Respiratory Tract Infections

Pneumonia is the second most common healthcare-related infection linked with the Enterobacteriaceae (30.6 percent, NHSN 2009 to 2010 survey). For patients with known risk factors (intubation, comorbidities), Enterobacteriaceae are among the top five etiological agents recovered in severe early onset (<5 days of hospitalization) healthcare-related pneumonias (*Enterobacter*, *Klebsiella*, and *E. coli*) and late onset (>5 days hospitalization) pneumonias (Enterobacter, other Gram-negative rods, *Klebsiella,*and *E. coli)*.[21,22,23]

*Klebsiella*species (10.1 percent, *n*= 854) were the most frequent Enterobacteriaceae recovered from VAP in the 2009 to 2010 NHSN survey. It was the third most frequent pathogen isolated from healthcare-associated pneumonia. This was followed by *Enterobacter*species (8.6 percent, *n*= 827, ranked no. 4), *E. coli* (5.9 percent, *n*= 504, ranked no. 6), *Serratia*species (4.6 percent, *n*= 386, ranked no. 7), and Proteus species (1.4 percent, *n*= 114, not ranked in the top 10 pathogens).[22]

Patients with healthcare-associated pneumonias in acute care facilities are often debilitated, ventilator-dependent, and have been previously colonized or exposed to aspirated oropharyngeal contents. Other risk factors include prolonged broad-spectrum antibiotic therapy, increased gastric pH, or loss of fibronectin.[1,2,3,4]Enteric community-associated pneumonias usually involve patients with underlying disease, alcoholics, or the malnourished. Organisms include *Klebsiella pneumoniae*and *Enterobacter*species and, to a lesser extent, *E. coli.*Gram-negative enterics also play an important role

in nursing home pneumonias. Patients with reduced cough reflex or compromised lung capacity are at greater risk in all settings.[1,3,4,5,22]

Management of "enteric" pneumonia remains important and demanding. These organisms are more likely to be multidrug resistant and form biofilm. Efforts to delay colonization, avoidance or reduction of time on ventilators, compliance with hand-washing protocols, and proper patient positioning can lessen the incidence of healthcare-associated pneumonias.

Recommendations and strategies to prevent VAP include active surveillance, educating personnel in the care of VAP patients and their equipment, applying a multidisciplinary approach, and increasing accountability.[27]

Urinary Tract Infections

Enterobacteriaceae are important etiologic agents of both community-associated and healthcare-associated urinary tract infections. Infections may range from painful urination to severe systemic illness. Severe infections may progress to sepsis, which may be fatal.

Sexually active women are at highest risk for community-associated infections. The single most important risk factor for HAIs is catheterization or obstructed urinary flow. Frequent risk factors associated with catheterization include duration of urinary catheterization, absence of antibiotic use, female gender, absence of use of a urinometer, microbial colonization of the drainage bag, diabetes mellitus, abnormal serum creatinine, and improper catheter care.[8,28,29,30]

Enterobacteriaceae were the leading cause of CAUTI (47.9 percent) in the 2009 to 2010 NHSN survey. *E. coli*(26.8 percent, *n*= 5,660) was the top pathogen recovered from CAUTIs. This was followed by *Klebsiella*species (11.2 percent, *n*= 2,365, ranked no. 3), *Proteus*species (4.8 percent, *n*= 1,013, ranked no. 6), *Enterobacter*species (4.2 percent, *n*= 880, ranked no. 8), and *Serratia*species (1.0 percent, *n*= 204, not in the top 10).[22,24,31]

In two point prevalence surveys (survey 1, July 2010 to January 2011; survey 2, January 2011 to July 2011) in the Chicago area, Lin et al. found a high rate of *Klebsiella pneumoniae*carbapenemase (KPC) colonization among 24 short-stay and 7 long-term acute care hospitals (LTACHs). Among LTACHs, 30.4 percent (119/391) of patients were colonized with KPC-producing Enterobacteriaceae, compared to 3.3 percent (30 of 910) of short-stay hospital ICU patients. Long-term care facilities may play an important role as reservoirs and in the dissemination of these extremely drug-resistant pathogens.[32]

Prevention and control of healthcare-associated CAUTIs includes education of personnel on the insertion and care of catheters, surveillance, avoidance of catheterization when possible, reduced duration of catheterization, and adherence to Standard Precautions.[29,30]

Surgical Site Infections

In the 1990 to 1996 NNIS, Enterobacteriaceae accounted for approximately one-fourth of incisional SSIs. This was a 25 percent decline since the 1980 to 1982 report.[24,31,33]The frequency of the organism recovered is dependent on the type of surgery and is usually resident flora.[24,31,33]Common pathogens include *E. coli, Enterobacter*species, *Klebsiella*species, and *Proteus*species.

Enteric pathogens constituted 22.4 percent of SSIs in the 2009 to 2010 NHSN survey. *E. coli*(9.4 percent, *n*= 1,981) was the most frequent pathogen and ranked number 3 among the top 10 pathogens responsible for SSIs. Other members included *Enterobacter*species (4.0 percent, *n*= 849, ranked no. 6), *Klebsiella*species (4.0 percent, *n*= 844, ranked no. 7), *Proteus*species (3.2 percent, *n*= 667, ranked no. 9), and *Serratia*species (1.8 percent, *n*= 385, not in the top 10). Antibiotic prophylaxis or empiric therapy with third-generation cephalosporins may selectively allow overgrowth of resistant isolates. Proper attention to aseptic techniques, appropriate prophylactic antibiotics, minimal organ manipulation, and shorter surgery times may assist in reduction of this type of infection. Other recommendations include education, surveillance, risk assessment, and accountability.[22,34]

Central Nervous System Infections

HAIs of the central nervous system (CNS) occur in neurosurgical patients, neonates, and patients undergoing procedures that penetrate the CNS. Premature or low-birth-weight infants are at particular risk for infections with *E. coli,*and *K. pneumoniae*and, less frequently, *Citrobacter diversus*and *Serratia marcescens*.[1,2,3,4]In the latest NHSN survey (2009 to 2010), Enterobacteriaceae accounted for 2 percent of SSIs. *Enterobacter*species (7.2 percent, *n*= 31) was the most frequently recovered Gram-negative rod recovered from neurological surgery. Other members of the Enterobacteriaceae recovered from CNS infections included *Klebsiella*species (3.5 percent, *n*= 15), *E. coli*(2.8 percent, *n*= 12), *Serratia*species (2.1 percent, *n*= 9), and *Proteus*species (0.9 percent, *n*= 4).

Gastrointestinal Tract Infections

Acute gastroenteritis and infectious diarrhea are caused by several members of the Enterobacteriaceae. *E. coli, Salmonella*species, and *Shigella sonnei*are the most common.[4,35]Enterotoxigenic strains of *Klebsiella, Enterobacter, Serratia, Citrobacter,*and *Proteus*have been isolated from infants and children with acute gastroenteritis.[1,3,4,36]Infections are usually the result of contact with infected individuals or consumption of contaminated food, water, milk, or other beverages. Exposure to contaminated fomites or environmental surfaces account for fewer cases. Transmission is via the fecal-oral route.[4]

Globally, annual deaths due to acute diarrheal diseases occur predominantly in young children. Rates in some countries are 1,000-fold higher than rates in the United States. Some populations in the United States, however, have diarrhea rates (and living conditions) that approach those seen in developing countries. Annual diarrheal death rates in the United States range from 500 to 10,000 cases. Patients or populations at greatest risk include infants, children, the elderly, the immunocompromised, and populations in custodial institutions. Laboratory workers, who handle infectious materials, are also at risk for acquiring these infections.[35,37]

Summary data from the Foodborne Disease Active Surveillance Network (FoodNet) revealed 19,089 infections, 4,247 hospitalizations, and 68 deaths. Infections with *Salmonella*species were the most common reported enteric disease (17.6 illnesses per 100,000 persons) and were associated with the largest number of hospitalizations (2,290) and deaths (29). Shiga toxin-producing *E. coli*(STEC) O157 infection caused 0.9 illnesses per 100,000. For the other enteric pathogens, the number of infections and incidence included: *Shigella*(1,780; 3.8 per 100,000), STEC non-O157 (451; 1.0 per 100,000); STEC O157 (442; 0.9 per 100,000), and *Yersinia*(159; 0.3 per 100,000).[35]

Keys to the prevention and control of infectious diarrhea incorporate proper infection control interventions, hand washing compliance, implementation of Standard and Transmission-based

Precautions, avoidance of undercooked meat or seafood, avoidance of unpasteurized milk or soft cheeses, and selective use of available typhoid vaccines for travelers to areas where typhoid is endemic.[36]

COMMON PATHOGENS—NONGASTROINTESTINAL (TABLE 75-1)

Escherichia coli

*E. coli*is the most common cause of community- and healthcare-associated urinary tract and bloodstream infections. It is the most common enteric recovered from the aerobic bowel flora. *E. coli*may also be recovered in HAIs such as neonatal meningitis, wound infections, and peritonitis. Colonization of the lower respiratory tract may happen without causing disease. *E. coli*is an uncommon cause of community-associated pneumonias, but is the third leading cause in hospitalized patients. It was the most frequently recovered Enterobacteriaceae (39.9 percent, *n*= 9,351) in the 2009 to 2010 NHSN survey and ranked in the top 10 recovered pathogens for CAUTI (no. 1), CLBSI (no. 9), VAP (no. 6), and SSI (no. 3).[22]

Increasing resistance to the beta lactams in general and the carbapenems specifically is a mounting public health concern.[2,36,38,39]

Enterobacter species

The *Enterobacter*species are increasingly important causes of HAIs due to emergence of highly resistant isolates. Most frequently encountered members include *Enterobacter cloacae, Enterobacter aerogenes,*and *Enterobacter agglomerans.*Although community-associated infections are rare, *Enterobacter*species are "opportunists," causing healthcare-related infections in the compromised or debilitated patient. They may also colonize the respiratory and urinary tracts, wounds, decubitus ulcers, and other sites. Clinical syndromes include lower respiratory tract infections, urinary tract infections, and septicemias and wound infections. Patients on prolonged periods of broad-spectrum antimicrobial therapy or ventilators appear to be at greatest risk for acquiring infection.

Treatment of *Enterobacter*infections is quite challenging. Emergence of multidrug-resistant isolates associated with carbapenemase, and other extended-spectrum beta-lactamase (ESBL) producers, coupled with the selection of resistant mutants during therapy, all contribute to the difficulty of treating *Enterobacter*infections. Consultation with an infectious disease specialist and laboratory evaluation of these isolates are mandatory for effective therapy and management.[2,4,15,40,41,42,43,44]

Klebsiella species

Virulence factors for *Klebsiella*species include a large capsule and LPS (endotoxins). *Klebsiella*species are responsible for community-associated and healthcare-related respiratory infections. The hallmark community infection is primary lobar pneumonia. Patients present with fever, shortness of breath, and purulent sputum with a currant jelly appearance. The currant jelly appearance is due to a mixture of blood and necrotic lung tissue. This type of necrotizing infection is often seen in alcoholics and patients with chronic or debilitating underlying disease. Less frequently encountered community respiratory infections included bronchitis and bronchopneumonia.[15,19,45,46,47]

Healthcare-related pneumonias are seen in nursing homes, debilitated patients, and ventilator-dependent patients. *Klebsiella*species (*K. pneumoniae, K. oxytoca*) may also asymptomatically colonize the upper respiratory tract of patients in long-term and acute care facilities without causing disease. Bacteremia

and urinary tract infections with *Klebsiella pneumoniae*are often recovered from patients with indwelling catheters. Enteropathogenic *K. pneumoniae*strains have been isolated from infants with diarrhea.[15,19,45,46,47]

Treatment of *Klebsiella*infections have become problematic is several regions of the country due to increasing prevalence of carbapenemase-producing strains. These strains produce broad-spectrum beta lactamases that inactivate all beta lactams including imipenem, meropenem, ertapenem, and aztreonam. They often carry plasmids and transposons that further confer resistance to multiple classes of other antibiotics (e.g., aminoglycosides, fluoroquinolones) and facilitate dispersion and transmission.[15,19,45,46,47]

Carbapenem-resistant *Klebsiella*pneumonia (CRKP) is the most frequently isolated carbapenemase-producing Enterobacteriaceae.

COMMON PATHOGENS—GASTROINTESTINAL (TABLE 75-2)

Escherichia coli Infections

Enteropathogenic or diarrheagenic *E. coli*strains are important sources of morbidity and mortality in emerging and developed nations. Infants and children are the largest at-risk populations. At least seven diarrheagenic *E. coli*strains have been associated with human disease. Only five are well characterized: enterotoxigenic (ETEC), enteroinvasive (EIEC), enteropathogenic (EPEC), enterohemorrhagic (EHEC), and enteroaggressive (EAggEC). Diarrhea-associated hemolytic *E. coli*(DHEC) and cytolethal distending toxin-producing *E. coli*(CDTEC) are newly identified strains, and their role in enteric disease is controversial.[35,36,38,39]

ETEC is a major cause of gastroenteritis worldwide. Infants and children are commonly affected in areas with poor sanitation. ETEC is also the cause of traveler's diarrhea. Most of these cases are due to ingestion of contaminated food or water while traveling in endemic areas. Symptomatic disease develops after a 1- to 2-day incubation and may persist up to 4 days. Patients present with a profuse, watery diarrhea, cramps, nausea, vomiting, and dehydration. Symptoms are due to the actions of two plasmid-mediated enterotoxins, one heat labile (LT) and one heat stable (ST). The heat-labile toxin is similar to that produced by *V. cholera*and stimulates hypersecretion of fluids and electrolytes. Diagnostic tests include EIA for enterotoxins and cell culture for cytotoxicity.[36,38,39]

EIEC produces bacillary dysentery-like illness with invasion and destruction of the colonic epithelium. Attachment and invasion is plasmid mediated. Foreign travel and contaminated food and water are important risk factors. Patients present with fever, cramps, watery diarrhea that progress to dysentery, and blood, mucus, and leukocytes in the scant stools. Confirmation is by observation of cytopathic effect of HeLa cell culture.[36,38,39]

EPEC is a major cause of infantile diarrhea in impoverished nations. Outbreaks of EPEC have occurred in U.S. nurseries. Children >2 years of age are most commonly affected. Disease is caused by a plasmid-mediated adherence and destruction of epithelial cells. Symptoms include watery diarrhea, fever, nausea, vomiting, and mucus in nonbloody stool. Diagnostic tests include adherence to Hep2 cells.[36,38,39]

EAggEC is a significant cause of diarrhea in developing nations and has been associated with a persistent, watery diarrhea with vomiting and dehydration in infants. A type of traveler's diarrhea has

also been associated with this species. Pathogenicity has not been established. A toxin and a hemolysin have been detected, but their role in disease is uncertain.[36,38,39]

EHEC, also known as STEC-Shiga-toxin producing *E. coli*(Table 75-2), is further discussed in **83. Foodborne Illnesses**.

Shigella Infections

Infection with species of *Shigella*ranges from asymptomatic to severe bacillary dysentery. Abdominal cramps, diarrhea, fever, and bloody stools characterize bacillary dysentery. Symptoms are mediated by an exotoxin or SHIGA toxin, which is neurotoxic, cytotoxic, and enterotoxic. Organisms invade, multiply, and damage the colonic mucosa. Disease progresses from a watery diarrhea to dysentery with frequent small stools containing blood and mucus, tenesmus, cramps, and fever. As little as 200 organisms (10^2) can initiate disease. The A subunit of the Shiga toxin adheres to small intestine receptors and blocks absorption of electrolytes, glucose, and amino acids from the intestinal lumen (enterotoxic). The B subunit binds host-cell glycolipid in the large intestines, prohibiting protein synthesis and cell death (cytotoxic).[4,36]

Four species with more than 45 O serotypes have been documented: *Shigella dysenteriae*causes the most severe form of bacillary dysentery, *Shigella flexneri*is the most common cause of shigellosis in developing nations, *Shigella sonnei*is the most common cause of shigellosis in United States and other developed nations. Humans and other higher primates are the only natural reservoirs. *Shigella*species can be recovered in 15 to 20 percent of the pediatric diarrhea in the United States and is a major cause of diarrheal disease in developing nations. Transmission is person to person via the fecal-oral route (primarily by contaminated hands). Secondary transmission frequently occurs.[4,36]

Salmonella Infections

How many, and what name to assign to, species belonging to the genus *Salmonella*can be confusing. Taxonomically, all strains of *Salmonella*belong to two species—*Salmonella enterica,*recovered from humans and warm-blooded animals, and *Salmonella bongori*, recovered from reptiles and the environment. Each species is further divided into subspecies and serovars. All human species would be classified as serovars within subspecies group 1 of *S. enterica*. The new nomenclature would change *Salmonella typhi*to *Salmonella enterica*serovar typhi, written as *S. typhi*.[23]The preceding nomenclature has not caught on, and the genus continues to be recognized by the more familiar names (*S. enteritidis, S. typhi, S. typhimurium, S. choleraesuis,*and *S. paratyphi*), which are based on serologic typing and geographic origin. Only about 200 of the known 2,000 or more serotypes are recovered in the United States each year.[36,48,49,50]

*Salmonella*species are ubiquitous in nature and are commensals of many animals, including poultry, birds, reptiles, livestock, rodents, domestic pets, and humans. Humans are the only reservoirs for *S. typhi*and *S. paratyphi.*Human illness is linked to ingestion of foods or water contaminated by feces of an infected animal or person. The required infective dose is very high (10^{6-8}organisms). Multiplication in food is necessary for transmission and symptomatic disease. Common source outbreaks have included raw and undercooked eggs and egg products, dairy products, fruits, vegetables, pet turtles, marijuana, and rarely food handlers. Fecal-oral transmission from person to person is important. Worldwide more than 3 million cases of *Salmonella*are reported each year. In the United States, more than 50,000 cases are reported annually. This is only 10 percent of the actual cases. Populations at greatest risk are children under 5, adults greater than 60 years, and patients with AIDS and sickle cell disease. Men who

have sex with other men are also at increased risk. *Salmonella*strains are able to invade and multiply in the gut, invoking an inflammatory response and stimulation of active fluid secretion.[36,48,49,50]

Four clinical syndromes are associated with *Salmonella*infections: enteritidis, septicemia, enteric fever, and asymptomatic carrier.[36,48,49,50]Enteritis:Symptoms appear 6 to 48 hours after ingestion of contaminated food or water. These may include nausea, vomiting, nonbloody diarrhea, fever, abdominal cramps, and myalgias and may persist from 2 to 7 days. No treatment is required. Septicemia:In severe cases, *Salmonella*may invade the bloodstream. Populations at greatest risk are at the extremes of ages and persons who are HIV positive. Complications include osteomyelitis, endocarditis, and arthritis. Enteric fever:Onset occurs 10 to 14 days after ingestion. Patients present with nonspecific febrile illness and may complain of headache, myalgias, malaise, and anorexia. The duration may last several weeks with progression to gastrointestinal invasion. Following the initial bacteremic phase, colonization of the gallbladder can occur. Asymptomatic carrier:*S. typhi*and *S. paratyphi*strains may be maintained in the carrier state by humans. About 1 to 5 percent of patients will become chronic carriers. The gallbladder is the reservoir in most patients.

Multidrug resistance among the *Salmonella*is increasing. Therapy should be guided by in vitro susceptibility testing and consultation with ID services.[36,48,49,50]

Yersinia Infections

The genus *Yersinia*is composed of 11 species. Only three are of immediate interest to infectious disease personnel. These are *Y. pestis*, *Y. enterocolitica,*and *Y. pseudotuberculosis.*Yersiniosis is a zoonotic disease and involves both intestinal and extraintestinal sites. *Y. enterocolitica*and *Y. pseudotuberculosis*are largely enteric pathogens responsible for acute bacteria enteritis. Patients infected with *Yersinia*present with an acute, febrile diarrhea, enterocolitis, or an acute mesenteric lymphadenitis, which mimics appendicitis. Natural reservoirs are wild and domestic birds and animals. Humans are accidental hosts.[2,51,52,53,54]

Enteric disease is the result of ingestion of contaminated food and water or by contact with infected people or animals. The highest isolation rates occur during the winter season in temperate climates, including northern Europe and North and South America. Common outbreak vehicles have included tofu, raw or undercooked pork, and milk. The incubation period is 3 to 7 days.[12,23,24]

Nonenteric diseases for these strains include septicemia, arthritis, intraabdominal abscess, hepatitis, osteomyelitis, and blood transfusion-related bacteremia and endotoxic shock. *Y. enterocolitica*survives at 4°C or refrigerated temperatures and can multiply to toxic levels in contaminated blood products. There are no reliable detection methods to rule out the presence of this microorganism in the blood supply.[51,52,53,54,55,56,57,58,59,60,61,62]

Human plague is normally a zoonotic disease following the bite of an infected flea or rarely by direct inhalation or handling of contaminated animal tissues or fluids. Rodents are the natural reservoir of *Y. pestis.*Reservoirs (infected fleas) are maintained in two epidemiological forms. In urban plague (black plague), the disease is preserved in rat populations and spread among rats or to humans by infected fleas. Control of rat populations can eliminate this natural reservoir.[63,64]

The second, sylvatic plague, is difficult to eliminate, because reservoirs are multiple (prairie dogs, mice, rabbits, rats, and domestic animals) and widespread. Patients become symptomatic 2 to 8 days

following the bite of an infected flea. Resultant clinical disease may occur in several forms.[4'54'62'65]

BUBONIC PLAGUE

The most common naturally occurring human disease symptoms include fever, chills, weakness, and development of an acutely swollen, tender lymph node or bubo in the groin, axilla, or cervical regions. Buboes are usually very painful. Bubonic plague has a 14 to 75 percent fatality rate. No person-to-person spread has been identified.

Primary Septicemia Plague

A minority of patients will develop sepsis with no discernible bubo. Secondary sepsis may arise from bubonic plague. In advance disease, gangrene of fingers and toes may occur ("black death"). Primary septicemic plague is not spread directly person to person. Case fatality rates range from 22 to 100 percent.

Primary Pneumonic Plague

Inhalation of plague bacilli results in primary pneumonic plague. Incidence is rare in the United States. Ninety percent of the cases are fatal. Patients are highly infectious and spread the disease by respiratory droplet. Symptoms include fever, cough, mucopurulent sputum, hemoptysis, and chest pain. The chest x-ray is usually consistent with bronchopneumonia. Secondary pneumonic plague may develop in a few patients with bubonic or septicemic plague via hematogenous spread to the lungs. Common symptoms are those of severe bronchopneumonia, chest pain, dyspnea, cough, and hemoptysis.[4'54'62'65]

Plague Meningitis

Plague meningitis follows the hematogenous seeding of the organisms into the meninges and is associated with fever and meningitis.

Plague Pharyngitis

Plague pharyngitis follows inhalation or ingestion of plague bacilli and is associated with cervical lymphadenopathy.[4'54'62'65]

Enterobacteriaceae as Biological Weapons

*Yersinia pestis*is a high-impact biological agent that presents a heightened bioterrorism risk. The epidemiology of plague following its use as a biological weapon would differ significantly from that of naturally occurring disease. Exposure would be more likely to be in the form of an aerosol. Outbreaks of pneumonic plague would result with symptoms initially resembling the flu or other severe respiratory infections. Healthcare facilities could be overwhelmed. There are no rapid diagnostics for detection of the organism. Current infection control interventions to prevent person-to-person spread of pneumonic plague are limited with little data available to make specific recommendations regarding appropriate measures. Available evidence indicates that person-to-person transmission occurs via respiratory droplets.[26]Recommendations in the APIC and CDC Bioterrorism Readiness Plan include the use of

Standard Precautions plus Droplet Precautions. Consult the APIC and CDC Bioterrorism Readiness Plan for details on patient placement, transport, cohorting, and postexposure management.[2'4'54'62'63'65'66]

OTHER ENTEROBACTERIACEAE AS BIOLOGICAL WEAPONS

Biological warfare is a serious and continuing threat. Healthcare providers must remain vigilant and alert to illness patterns and diagnostic clues that might indicate an unusual infectious disease outbreak associated with intentional release of a biological agent.[28,29] We must think outside the box to detect nontraditional disease presentation and possible agents. Several members of the Enterobacteriaceae have potential for use as biological weapons (Table 75-4). Two species, *Y. pestis*[26] and *Salmonella*[30] species, already have been dispersed with harmful intent. At least one, again *Y. pestis,* has been listed as a Category A agent in the CDC assessment of potential biological terrorism agents.[29] Agents in Category A present the greatest threat to the public in terms of illness and deaths. They require focused and determined efforts to improve surveillance and laboratory diagnosis.

Table 75-4 Common ESBLS and Carbapenemases Associated With Enterobacteriaceae

Beta-lactamases TYPE	Class	Description	Common Enterobacteriaceae species	Possible Alternative Therapy*
Extended-spectrum beta-lactamases				
TEM ESBLs	A	ESBLs (serine-dependent) derived from mutations in the *TEM-1, TEM-2* genes. They have varying hydrolysis profiles which include penicillins, broad- and extended-spectrum cephalosporins, and monobactams. These enzymes are inhibited by clavulanic acid. Most are carried on plasmids or transposons. TEM is name after a Greek patient (TEMoniera) from which it was first isolated.	*Klebsiella* species *Escherichia coli* *Proteus mirabilis* *Citrobacter freundii* *Serratia marcescens* (they can share among the family)	Imipenem Imipenem/cilastin Meropenem Aminoglycosides Fluoroquinolones Tigecycline
SHV ESBLs	A	ESBLs derived from mutations in the *SHV-1*. SHV (sulphydryl variable) enzymes are mainly cephalosporinases and are inhibited by clavulanic acid. These confer resistance to cefotaxime and ceftazidime by hydrolyzing cefotaxime and to a lesser degree ceftazidime.	*Enterobacter*species *Citrobacter*species *Klebsiella pneumoniae*	Imipenem Imipenem/cilastin Meropenem Aminoglycosides Fluoroquinolones Tigecycline
AmpC ESBLs	C	Mainly chromosomally-mediated ESBLs that are inducible and capable of hydrolyzing broad- and extended-spectrum cephalosporins. They may also have some low level activity against the carbapenems. They are not inhibited by the clavulanic acid or other beta-lactamases inhibitors.	Enterobacter cloacae Serratia marcescens Citrobacter freundii Morganella morganii	Imipenem Meropenem Aminoglycosides Fluoroquinolones

CTX-M ESBLs	A	ESBLs that hydrolyze cefotaxime and to a lesser degree ceftazidime and aztreonam. They also have high affinity for cefepime. These are the most rapidly spreading ESBLs nationally and internationally and appearing with increasing frequency in the community. They are more readily inactivated by tazobactam than clavulanic acid and sulbactam.	*Escherichia coli* *Klebsiella pneumoniae* *Salmonella*species *Shigella*species *Citrobacter freundii* *Serratia marcescens*	Imipenem Imipenem/cilastin Meropenem Aminoglycosides Fluoroquinolones Tigecycline
Carbapenemases				
KPC 1-4	A	ESBLs that confer resistance to extended-spectrum cephalosporins and carbapenems. Enzymes are inhibited by clavulanic acid. K*lebsiella*p*neumoniae*carbapenemases are mostly plasmid mediated. KPC-1 (North Carolina), KPC-2 (Baltimore), and KPC-3 (most frequent, New York), KPC-4 (Scotland). High potential for spread. Mainly isolated on the U.S. East Coast. The most common carbapenemases.	*Klebsiella pneumoniae* *Klebsiella oxytoca* *Salmonella enterica* *Enterobacter* species	Aminoglycosides Fluoroquinolones Polymyxins Tigecycline Colistin
SMC1-3		Chromosomally mediated carbapenemases.	*Serratia marcescens*	As above
IMI-1		Chromosomally mediated carbapenemases.	*Enterobacter cloacae*	As above
MBL	B	ESBLs-metallo-beta-lactamase with a zinc rather than a serine core. Have broad-spectrum activity. Capable of hydrolyzing all penicillins, cephalosporins, monobactams (except aztreonam), and carbapenems. Affinity for imipenem and other carbapenems varies. These are inhibited by EDTA, but not clavulanic acid.	*Serratia marcescens* *Klebsiella pneumoniae*	Aminoglycosides Fluoroquinolones Aztreonam
	NDM	New Delhi, novel MBL, emerged in 2009 from Swedish patient after medical care in India. Confers "pan-resistance" with 50 percent mortality; hydrolyzes all penicillins, cephalosporins, and carbapenems.	*Klebsiella pneumoniae* *Escherichia coli* *Enterobacter cloacae*	Very limited options (combination therapy is warranted), colistin, tigecycline
OXA-48, OXA-181	D	Carbapenemase enzymes that preferentially hydrolyze oxacillin. Those with activity against Enterobacter are mainly OXA-48. Have a peculiar profile, weakly hydrolyzes carbapenems, with low level activity against cefotaxime, no activity against ceftazidime or other third-generation cephalosporin. They are not inhibited by clavulanic acid.	*Enterobacter* species *Klebsiella pneumoniae* *Escherichia coli*	Ceftazidime Colistin Aminoglycosides Fluoroquinolones Polymyxin

Enteric pathogens such as *Salmonella*, *Shigella,*and enterotoxigenic *E. coli*may be used to threaten or compromise our food supply. These organisms are one tier down in Category B. These organisms have the potential to cause widespread disease, but less serious illness and deaths. Category C is reserved for those biological agents that are currently not believed to present a high bioterrorism risk but might emerge in the future.[67,68]

LABORATORY IDENTIFICATION

No special requirements, except those in place for routine collection and transport of specimens, are needed to recover the Enterobacteriaceae from sources outside the gastrointestinal tract. Pus, sputum, blood, tissue, and other sterile specimens should be collected and processed according to routine microbiological protocol. Specimens (stools, rectal swabs) to rule out enteric pathogens should be collected fresh and delivered to the microbiology laboratory within 2 hours. Samples should be placed in an adequate transport media (Stuart's, Cary-Blair) and refrigerated, if they cannot be delivered within the 2-hour time limit. Rectal swabs are a less desirable sample except in outbreak investigations.[1,3,4,15]

On Gram stain, the Enterobacteriaceae all appear as Gram-negative coccobacilli or rods with no distinguishing characteristics. Special stains such as methylene blue or Wayson may highlight identifying characteristics (i.e., safety pin or bipolar staining characteristic of *Y. pestis*). Most Enterobacteriaceae grow readily on simple microbiological plating media and on media used for biochemical characterization. All members grow on routine laboratory media such as blood or MacConkey agar. Selective and differential agars such as HE (Hekton enteric), XLD (xylose-lysine-deochocolate), and SS (*Salmonella-Shigella*) agars are commonly used to isolate enteric pathogens from feces and other gastrointestinal sites. Enhanced recovery of enteropathogenic *E. coli*or *Yersinia*species may be aided by Sorbitol MacConkey (SMAC) agar or Cefsulodin-Irgasan-Novobiocin (CIN) agars, respectively.[1,3,4,15]

Microbiologists use commercial kits, automated systems, simple screening tests, and conventional biochemical tube tests for identification. With some automated systems and kits, the common pathogens may be identified in as little as 2 hours. Strains that have been exposed to prolonged antimicrobial therapy may no longer react typically in these systems and present identification problems for the laboratory. Because of the expanding number of Enterobacteriaceae, current automated and commercial kits may have problems identifying emerging pathogens (i.e., *Hafnia alvei*[gastroenteritis], *Rahnella aquatilis*[HAIs in immunocompromised patients]).[1,2,3,4,15]

Molecular probes and nucleic acid amplification techniques are also increasingly used to rapidly identify enteric and emerging pathogens. A variety of phenotypic (biotyping, serotyping, antibiograms, bacteriocin. and phage typing) and genotypic (plasmid analysis, restriction fragment length polymorphism, ribotyping, polymerase chain reaction [PCR], pulse-field gel electrophoresis, DNA probes, and DNA sequencing) methods are used for epidemiological investigations. New technologies such as the mass spectrometer are being used to more efficiently identify new and older species. This technology affords a more rapid and accurate identification.[69,70]

TREATMENT

Empirical therapy for the Enterobacteriaceae is no longer predictable. Selection of antibiotic therapy for infections with Enterobacteriaceae must be guided by in vitro susceptibility test results, local antibiotic pressures, and clinical experience. Knowledge of the local resistant trends is important for management and appropriate selection of empirical therapy. Patterns will vary dependent on the patient population, prescribing formulary, usage, testing system, and clinical practice.[71,72]

Intrinsic resistance to first-generation cephalosporins and ampicillin is a genetic property of several Enterobacteriaceae. Resistance to additional or multiple antimicrobials may be acquired by acquisition of extrachromosomal genes (plasmids, transposons, etc.) or through chromosomal modification or mutation. Common resistant mechanisms include production of antibiotic modifying enzymes (i.e., beta lactamases, ESBLs), decreased penetration into the cell (aminoglycosides), modification of the cell wall precursor (vancomycin), alteration of the ribosomal or enzyme target (macrolides, quinolones), efflux

mechanism (tetracyclines), and overproduction of targeted enzymes (sulfonamides). Mechanisms may be chromosomal or plasmid regulated.[73,74,75]

Although most members remain susceptible to the most frequently prescribed antimicrobials (i.e., fluoroquinolones, third-generation cephalosporins), others, especially *Enterobacter*, *Klebsiella,*and *Serratia*species, have emerged with resistance to multiple antibiotics.

The increasing prevalence of multidrug-resistant Enterobacteriaceae, especially those producing extended-spectrum beta-lactamases (ESBLs) capable of inactivating all beta-lactam antibiotics severely restricts therapy and threatens patient safety. More than 200 ESBLs have emerged among the Enterobacteriaceae associated with HAIs. The most common ESBL-producing pathogens included *Klebsiella*species and *E. coli*. The ESBL-resistant genes are carried on plasmids or other mobile genetic elements, along with resistance to the fluoroquinolones and aminoglycosides. They can readily be transmitted to other members of the family. Other beta-lactamases, AmpC, and carbapenem-producing Enterobacteriaceae (CPE) (Table 75-4) are capable of hydrolyzing most beta-lactam antibiotics. Multidrug resistance among the Enterobacteriaceae varies by ICU organisms, geographic regions, and country and is an increasing concern for all healthcare providers.[76,77,78,79,80,81,82,83]

In the 2009 to 2010 NHSN summary report comparing resistant rates, the highest multidrug resistance (16.8 percent) was documented for CLABSIs. Resistance to carbapenems (12.8 percent) was four times that for *E. coli*and *Enterobacter*species (both 3.7 percent). Broad-spectrum resistance to the cephalosporins was widespread and highest for *Enterobacter*isolates (Figure 75-3).[22,84]

CARBAPENEM-PRODUCING AND CARBAPENEM-RESISTANT ENTEROBACTERIACEAE

Among the most challenging and troublesome trends in the treatment of Enterobacteriaceae-associated HAIs is the emergence of resistance to the carbapenems. This is a worrisome trend because these drugs are usually the last option for the treatment of multidrug-resistant infections among our sickest patients. Even more daunting is that these carbapenem-resistant Enterobacteriaceae (CRE) may become members of the normal enteric flora and serve as reservoirs for community spread.

Carbapenemases are hydrolyzing enzymes that confer resistance to the expanded spectrum cephalosporins, monobactams, and the carbapenems (imipenem, meropenem, and ertapenem) (Table 75-4). The mechanism is due to the presence of genes (*bla*kpc*, bla*sme*, bla*vim) that are carried on conjugative plasmids or due to porin changes in cell membrane. The presence of a plasmid is often flanked by transposons that carry additional resistant mechanisms to fluoroquinolones and aminoglycosides.[85]

The carbapenemase family of enzymes include the *Klebsiellapneumoniae*carbapenemases (KPC-1, KPC-2, KPC-3), *Serratiamarcescens*enzyme (SME-1, *Serratia*species), and Verona integron-encoded metallo-beta-lactamase (VIM-1). They are predominantly of the KPC, VIM, IMP, NDM and OXA-48 types (Table 75-4).[6,83,86,87,88]

In the United States, most cases of have been reported from the East Coast and recovered mainly from *K. pneumoniae*with sporadic isolation from other Enterobacteriaceae including *Klebsiella oxytoca*, *Citrobacter freundii*, *Salmonella*ssp., *Enterobacter*spp., and *E. coli.*

KPC producing *K. pneumoniae*have become endemic in the Northeast but have been reported from at least 42 states.[13,14]

Surveillance (NHSN) data collected during the first months of 2012 estimated that at least one CRE HAI was documented in 4.6 percent of acute care hospitals, 3.9 percent of short-stay hospitals, and 17.8 percent of long-term acute care hospitals in patients with a CAUTI or CLABSI. Data from NNIS/NHSN (2001, 2011) and the Surveillance Network-USA (TSN) for 2001 and 2010 documented an increase in the percentages of NHSN CRE from 1.2 percent in 2001 to 4.2 percent. The rate for the TSN went from 0 percent in 2001 to 1.4 percent in 2010. This increase was fueled by a sixfold increase in carbapenem-producing *K. pneumoniae*.[89]

Laboratory Detection

The true incidence and prevalence of carbapenemase-producing or -resistant Enterobacteriaceae is not known. This is due in part to the lack of routine screening by most microbiology laboratories and the inadequacy of routine in vitro susceptibility tests (automated systems, disk diffusion, or E tests) to detect low-level resistance in carbapenemase-producing strains of Enterobacteriaceae.

In 2008, the Clinical and Laboratory Institute (CLSI) recommended using the modified Hodge test (MHT) to screen Enterobacteriaceae strains with elevated minimal inhibitory concentrations (2 to 4 µg/mL) to the carbapenems or reduced disk diffusion zones for the presence of carbapenemases.[90]

Anderson and colleagues evaluated the sensitivity of meropenem, imipenem, and ertapenem using disk diffusion, E tests, microbroth (reference method), and automated systems versus the modified Hodge test for documenting the presence of CPE, documenting greater than 90 percent sensitivity and specificity with only the reference microbroth dilution method (BMD) and the modified Hodge test. Ertapenem was the most sensitive for detecting low level resistance. The modified Hodge test was 100 percent sensitive and specific for the presence of carbapenemases. It is a phenotypic test and is not specific for the KPC enzymes. PCR techniques are currently the most reliable method for confirming the presence of KPC enzymes.[91]

In 2010, CLSI revised carbapenem susceptible breakpoints for ertapenem (S ≤0.25 µg/mL), imipenem (S ≤1 µg/mL), and meropenem (S ≤1 µg/mL) and established a new breakpoint for doripenem (S ≤1 µg/mL). MICs outside these ranges are considered nonsusceptible and additional screening is required. The new breakpoints were established to eliminate the need for the MHT, which is time consuming, and to more accurately predict carbapenemases' outcomes.[92]

No change has been observed in the U.S. Food and Drug Administration breakpoints and many laboratories rely on the older, higher breakpoints and phenotypic tests to document the presence of carbapenemase-producing strains. This may result in missed opportunities isolated with low level production.[83]

Prevention measures for containment and identification of colonized patients in low, endemic, or during outbreaks should include implementation of the tier 2 recommendations for multidrug-resistant organisms, and the collection of rectal swabs for screening asymptomatic and high risk patients. Updated recommendations for the detection, monitoring, and control of CRE are outlined in the 2009 CDC *Guidelines for Control of CRE in Acute Care and Long-term Care Facilities*and the 2010 CRE toolkit.[13,14,93]

Fluoroquinolones

Fluoroquinolone resistance among Enterobacteriaceae may result in clinical failure and compromise outcomes. The majority of resistance to fluoroquinolones among the Enterobacteriaceae is chromosomally mediated. Recently, plasmid-mediated resistance has emergence to both third-generation cephalosporins and quinolones. This coresistance further reduces the selection and use of antibiotics to treat these HAIs in the hospital and the community.[74,80,94,95,96]

New Therapeutic Options for the Enterobacteriaceae

Colistin and polymyxins are alternative antibiotics for the treatment of CPE and other multidrug-resistant strains and may be included singularly or in combination with other antibiotics. However, heteroresistance and declining resistance for *Enterobacter*species have been documented.[97,98]

In a retrospective study of patients from Barnes Jewish hospital (June 1, 2006 to February 1, 2008) with clinical and microbiological KPC bacteremia, in vitro testing revealed high susceptibility rates for tigecycline (28/29 [97 percent]), minocycline (22/29 [76 percent]), and fosfomycin (25/29 [86 percent]) against the KPC-positive isolates.

van Duin and colleagues also identified aminoglycosides, tigecycline, and temocillin as additional drugs used in the treatment of CREs. Issues include limited efficacy, increasing resistance, and multiple toxicities.[88]

Few therapeutic options remain for treating multidrug-resistant Enterobacteriaceae. Current approaches include use of drug combinations and older drugs. In addition, there are new drugs in the pipeline for management.[35,87,99,100]

Strategies required to manage and reduce antibiotic resistance include ongoing surveillance, molecular epidemiological techniques, hand hygiene, antimicrobial controls, and administration support.[21,35,88]

Applicable Guidelines

Guidelines for the prevention and control of HAIs have been published by the CDC and several professional societies. The global *Compendium of Strategies to Prevent Healthcare-associated Infections in Acute Care Hospitals*is important in reestablishing a culture of prevention and patient safety across the continuum of care. These can be downloaded from the CDC and/or the APIC Web page.

Recent and relevant guidelines released by the CDC are available at **www.cdc.gov**or **www.cdc.gov/hicpac/pubs.html**and include the 2012 CRE Toolkit - Guidance for Control of Carbapenem-resistant Enterobacteriaceae (CRE) guideline for the prevention of intravascular catheter-related infections and guidelines for prevention of catheter-associated urinary tract infections.

Guidance for control of infections with carbapenem-resistance or carbapenemase-producing Enterobacteriaceae in acute care facilities provides new guidance for CRE infection prevention and control in an effort to limit the further emergence of these organisms.

The 2008 guidelines for *Disinfection and Sterilization in Healthcare Facilities*provide evidence-based recommendations for the cleaning, disinfection, and sterilizing of patient care medical devices and

equipment as well as cleaning and disinfecting the healthcare environment in healthcare facilities. These are also available on the APIC website and/or as a download from the CDC.[101]

Other applicable guidelines include Guidelines for Isolation Precautions in Hospitals,[102]Guideline for Environmental Infection Control in Healthcare Facilities,[103]Hand Hygiene,[104]and Management of Multidrug-resistant Organisms in Healthcare Settings,[105]as well as:

APIC Elimination Guides for Prevention of Mediastinitis Surgical Site Infections(2008)

Guide to the Elimination of Catheter-Related Bloodstream Infections(2009)

Guide to the Elimination of Catheter-Associated Urinary Tract Infections(CAUTI) (2008)

Guide to the Elimination of Ventilator-Associated Pneumonia(2009)

The APIC elimination guidelines are available for download or purchase (**www.apic.org**) and provide the infection preventionist with evidence-based information for monitoring and reducing HAIs across the continuum of care.

Conclusions

Although incidence and prevalence of HAIs due to the Enterobacteriaceae may be declining, they remain important pathogens in all healthcare facilities. Enterobacteriaceae are among the top 10 pathogens recovered from the top four device-associated infections (CLABSI, CAUTI, VAP, and SSI). Non-*E. coli*enteropathogenic strains are emerging pathogens and increasingly implicated in healthcare- and community-associated diarrheal diseases.

Immediate challenges facing the infection prevention professionals in the 21st century include older and sicker patients, multidrug- and pan-resistant organisms, reduced staff, limited reimbursement, and diversity of healthcare settings. Infection preventionists must develop plans to focus surveillance on the high-risk patient populations while expanding and applying the principles of healthcare epidemiology to all settings.[71,106]

Reduction of HAIs as part of a larger "patient safety" campaign must be the focus of healthcare providers in all settings worldwide. Currently in the United States, hospital infections contribute to an estimated 90,000 deaths each year, with a staggering economic cost of $4.5 to $5.7 billion annually.[11,107]Occurrences of high incidences of preventable adverse events in international hospitals have also been reported.[11,107,108,109]

Research and evidence-based medicine algorithms to prevent infections and/or more quickly detect patients who are at risk are also on the agenda. More prudent use of antibiotics, increased barrier precautions, patient positioning, selective disinfection, use of silver alloy urinary catheters, and increased compliance to hand hygiene guidelines are practices and research initiatives targeted for reducing and preventing HAIs.[110,111,112,113]Implementing patient safety practices such as root cause analysis and continuous quality improvement are tools the infection preventionist can use to enhance their infection prevention and control practice.[114]It is a matter of patient safety and survival.

Future Trends

There has been a steady decline in the percentage of Enterobacteriaceae recovered from NNIS/NHSN hospitals in the last two decades.

Nevertheless, they remain leading causes of community- and healthcare-associated infections. In addition, increasing reports of resistance to the expanded spectrum cephalosporins, fluoroquinolones, and carbapenems severely compromise therapeutic options and patient outcomes in the United States and worldwide.

There is mounting public health concern about the emergence and spread of multidrug- and pan-resistant CPE and the dwindling arsenal of antibiotics for their management. Although, initially found only in acute care hospitals, they have been found as colonizers and in the feces and urine of nonsymptomatic patients in long-term care facilities that might serve as a reservoir. Infection preventionists and other healthcare providers must refocus their efforts to detect and protect patients from infections with these and other members of the Enterobacteriaceae.

International Perspective

HAIs are patient safety issues worldwide.[36,39]The Enterobacteriaceae are among the top five causes of infections in both developed and developing countries with prevalence ranging from 4 to 32 percent.[41,42,43]The most frequently involved infections in descending occurrence were SSIs, UITs, lower respiratory infections, and bloodstream infections.[109,115,116]

Increasing antibiotic resistance among healthcare-associated pathogens worldwide is emerging as one of the leading global public health issues. Worldwide resistance of the Enterobacteriaceae to third-generation cephalosporins and now the fluoroquinolones further reduces available therapeutic options and increases the risk for adverse patient outcomes.[73,75,79,117,118]CRE isolates due to KPC enzymes have been recovered in Europe, Asia, and South America. The class B metallo-beta-lactamases (MBLs), first identified in Japan, have disseminated globally with reports of isolates documented in the United States, Canada, England, Italy Australia, Korea, Malaysia, Brazil, Columbia, Singapore, Taiwan, and mainland China.

The New Delhi MBL (NDM-1) was first isolated from a Swedish patient hospitalized in India and since has spread and caused outbreaks in the United States, Europe, Asia, and Australia. Between January 2009 and February 2011, eight Enterobacteriaceae isolates with NDM-1 type production were reported to the CDC. All isolates were recovered from patients who had traveled to India or Pakistan for medical procedures.[83,119]

A second outbreak involving the *Klebsiella pneumoniae*and the NDM-I were reported to the CDC in 2012 from the Colorado Department of Public Health and Environment. Strains from the eight patients were molecularly linked. Reservoir or how the carbapenemase-producing *K. pneumoniae*strain entered the facility remains unclear.[120]

The first isolate of *K. pneumoniae*with OXA-48 was identified in Turkey since then Enterobacteriaceae with OXA-48-type enzymes have been recovered in Europe, the Middle East, and Northern Africa.[83,87,

119’121’122

Increased public surveillance, systematic approaches, and global collaboration are all necessary to help reduce the burden of preventable HAIs and improve patient safety worldwide.

APIC TEXT OF INFECTION CONTROL AND EPIDEMIOLOGY

Enterococci

Author(s): Lennox K. Archibald, MD, PhD, FRCP, DTM&H
Hospital Epidemiologist

Malcom Randall VA Medical Center
Gainesville, FL

Published: October 3, 2014

Abstract

Enterococcus*is an important organism because it is one of eight classes of pathogens that account for approximately 70 percent of healthcare-associated infections in the United States. This chapter reviews the bacteriology, epidemiology, and infection prevention elements of this organism, as well as diagnosis and treatment of the clinical diseases it produces. The use of active surveillance is discussed as an effective strategy for the reduction of vancomycin-resistant enterococci.*

Key Concepts

- Enterococci are Gram-positive, catalase-negative, nonspore-forming cocci that can exist singly, in pairs, or in chains. They grow under facultative anaerobic conditions, with optimum growth occurring at 35°C to 37°C.
- Enterococci typically colonize the human gastrointestinal and biliary tracts; less commonly, they colonize the female genital tract and male urethra, the perineum, the oral cavity, and the skin.
- Of the approximately 38 species, *Enterococcus faecalis*and *Enterococcus faecium*are the most common isolates encountered in the clinical setting; the former is associated with approximately 90 percent of human enterococcal infections, whereas the latter is associated with as many as 15 percent of such infections.
- *Enterococcus*is one of eight classes of pathogens that account for approximately 70 percent of healthcare-associated infections in U.S. hospitals.
- After vancomycin-resistant enterococci have been introduced into a healthcare setting, transmission is determined by selective pressure due to antimicrobial use, the proportion of colonized patients within the facility or unit, the number of susceptible patients within the setting, and adherence to prevention efforts by healthcare personnel.

- Active surveillance cultures for resistant pathogens in intensive care units with isolation of colonized persons appears to be an effective strategy for vancomycin-resistant enterococci control in some institutions; isolation purely on the basis of history of previous vancomycin-resistant enterococci detection appears to be of little benefit.
- Standard Precautions and isolation of the occasional patient recognized to be colonized through routine clinical cultures have not proved effective in reducing rates of vancomycin-resistant enterococci infections.

Bacteriology

*Enterococcus*species are Gram-positive, catalase-negative, nonspore-forming cocci that can exist singly, in pairs, or in chains. They grow under facultative anaerobic conditions with optimum growth occurring at 35°C to 37°C. Growth colonies are morphologically larger than those of streptococci and usually are nonhemolytic or α-hemolytic, though some enterococci strains may exhibit β-hemolysis. The name "enterococcus" reflects their tendency to reside in the human gastrointestinal tract, where their intrinsic properties give them the ability to survive in that environment. These properties include the ability of the majority of strains to grow at a wide range of temperature (10°C to 45°C) and pH (4.5 to 9.6) and the ability to maintain growth in the presence of high concentrations (6.5 percent) of sodium chloride and bile salts.[1]Other biochemical properties include the ability to hydrolyze esculin in the presence of 40 percent bile (bile-esculin [BE] test); the ability to hydrolyze leucine-β-naphthylamide to produce leucine aminopeptidase (LAP); and production of pyrrolidonyl arylamidase by hydrolyisis of pyrrolidonyl-β-naphthylamide (PYR). Presumptive identification of a Gram-positive coccus as an *Enterococcus*species in the medical microbiology laboratory can be made by demonstrating that the isolate grows in the presence of 6.5 percent sodium chloride at 45°C, is catalase-negative, and is positive for the BE, LAP, and PYR tests.[2]

*Enterococcus*species previously were classified with the *Streptococcus*genus that possesses the Lancefield group D antigen (lipoteichoic acid) in their cell walls.[1,2,3]During the mid to late 1980s, the application of DNA molecular techniques to group D streptococci taxonomy resulted in the reclassification of these streptococci into two genera—a distinct *Enterococcus*genus separate from group D streptococci.[3]The current criteria for belonging to the genus *Enterococcus*includes phenotypic testing as well as DNA typing and 16S rRNA gene sequencing.[2]Based on the analysis of 16S rRNA sequences, at least 38 species of *Enterococcus*have now been identified.[2]

Epidemiology

Enterococci are now considered the most abundant Gram-positive cocci that colonize the human gastrointestinal and biliary tracts. Less commonly, they colonize the female genital tract, the male urethra, the perineum, the oral cavity, and the skin. Certain *Enterococcus*species can be found in soil, water, food, plants, animals, birds, insects, and reptiles.[2]Most enterococcal infections occur in hospitalized patients, especially in the ICU setting. Of the approximately 38 species now identified, *Enterococcus faecalis*and *Enterococcus faecium*are the most common isolates encountered in the clinical setting; the former is associated with approximately 90 percent of human enterococcal infections and the latter is associated with up to 15 percent of such infections.[4,5,6]Other enterococcal species have been

infrequently associated with human infections, especially in the hospitalized compromised patient (Table 76-1). Although *E. faecalis*and *E. faecium*are microorganisms of low virulence, they are rendered pathogenic in debilitated and immunocompromised patients and those with comorbidities such as diabetes, chronic congestive heart failure, or chronic obstructive pulmonary disease, especially those receiving broad-spectrum antimicrobial therapy or having one or more in situ invasive medical devices (e.g., intravascular catheters, mechanical ventilators, urinary catheters).[7,8,9,10,11,12]

Although the major mode of spread of *Enterococcus*in healthcare settings in the United States is via direct or indirect contact transmission mediated by transient carriage on the hands of healthcare personnel (HCP), the actual chain of transmission of enterococci in healthcare settings remains a complex interplay of (1) the host (i.e., the patient) who might or might not be colonized; (2) the organism itself—generally innocuous in the normal healthy individual but rendered opportunistic in a susceptible host; and (3) the environment as defined above.[9,13]It is well documented that enterococci may remain viable for days to weeks on dry, inert, environmental surfaces (fomites), including clothing and laboratory coats. Such contaminated surfaces may act as a source or intermediary for direct or indirect contact transmission via the hands of HCP. Other sites of environmental contamination in healthcare facilities include thermometers, sphygmomanometers, stethoscopes, upholstery, bedrails, computer keyboards, white coats, ties, medicine preparation areas, patients' hospital clothing, linen, doorknobs, electrocardiogram monitors, intravenous fluid pumps, and commodes.[3,12,14,15,16,17,18,19,20,21,22,23,24,25,26,27,28]

After vancomycin-resistant enterococci (VRE) have been introduced into a healthcare setting, transmission is determined by selective pressure due to antimicrobial use, the proportion of colonized patients, the availability of susceptible patients, and adherence to prevention efforts.[29]Complicating the mechanism of transmission even further are various other risk factors, including the proportion of colonized patients already resident in the pertinent inpatient unit, the availability of susceptible patients, the degree of adherence to infection prevention efforts in the facility, staffing levels, severity of illness of susceptible patients, and the cellular factors that determine the virulence and pathogenicity of enterococci. Virulence factors, though not fully understood, include:

- Cytolysin, a hemolysin that causes β-hemolysis of human, rabbit, and equine but not sheep erythrocytes[14,30,31,32];

- Aggregation substance, a surface-bound, plasma-encoded protein that mediates adhesion to a variety of eukaryotic cell surfaces[33];
- Extracellular superoxide production[34];
- Enterococcal surface protein;
- Pheromones, small peptides that promote conjugative transfer of plasmid DNA[35];
- Bacteriocin, a plasmid-coded enzyme that lyses Gram-positive and Gram-negative bacteria; gelatinase; and hyaluronidase.

Most of these virulence factors have been identified in *E. faecalis*but have rarely been detected in other enterococcal species.[31]

Data from the National Healthcare Safety Network (NHSN) and the Centers for Disease Control and Prevention (CDC) indicate that among the eight pathogen groups that account for approximately 70 percent of healthcare-associated infections (HAIs) in U.S. hospitals, the three most commonly reported pathogens are *Staphylococcus aureus*(15.6 percent), *Enterococcus*spp. (13.9 percent), and *Escherichia coli*. Of the microorganisms that predominate among the four major infection sites (i.e., bloodstream, surgical wounds, respiratory tract, and urinary tract), *Enterococcus*spp. are the third most common cause of surgical site infections (SSIs) (12 percent) and the second most common cause of bloodstream infections (BSIs).[36]

The incidence and prevalence of VRE have been increasing significantly over the past two decades; these rate increases are clearly more marked in the intensive care unit (ICU) versus the non-ICU inpatient setting.[37,38]From 1989 to 2004, the proportion of ICU *Enterococcus*spp. infections that were caused by VRE and reported to the National Nosocomial Infections Surveillance (NNIS) system increased from 0.4 percent to more than 33 percent. This rate increase, in particular, is of enormous clinical importance because documentation during the 1990s showed that at least 83 percent of VRE isolates were resistant to most of the available antimicrobials.[39,40]Although newer agents like daptomycin and linezolid have proven effective against VRE, treatment options for patients with VRE HAIs remain limited, often to unproven combinations of other antimicrobials or experimental compounds.

Unfortunately, current data suggest that the number of hospitalizations with infection due to vancomycin-resistant pathogens is still increasing in the United States.[41]Other data from the Surveillance and Control of Pathogens of Epidemiological Importance (SCOPE) study, a multicenter surveillance system for bloodstream infections in the United States, have established that *Enterococcus*spp. are the third most common (9 percent) cause of healthcare-associated BSIs after coagulase-negative staphylococcus (31 percent) and *S. aureus*(20 percent)—consistent with CDC data.[42]

Antimicrobial Resistance And Susceptibility Testing Issues

Antimicrobial resistance among enterococci to a growing number of agents is increasing across the United States and can be a manifestation of their pathogenicity. Enterococci are inhibited by β-lactam agents (e.g., ampicillin) but generally are not killed by them. Such resistance may be intrinsic or acquired and can manifest at low or high levels to the agent of concern (Table 76-2).

Intrinsic resistance: Intrinsic resistance in enterococci is basically inherent resistance resulting from natural characteristics that are chromosomally encoded in the genome of the organism. Enterococci are inherently resistant to β-lactam agents (cephalosporins, penicillinase-resistant penicillins, and monobactams), aminoglycosides, and trimethoprim/sulfamethoxazole. The majority of strains express this intrinsic resistance in chromosomal resistance genes. Such strains may manifest intrinsic low-level resistance to various aminoglycosides or intermediate susceptibility or resistance to fluoroquinolones and are generally less susceptible than streptococci (10- to 1,000-fold) to penicillin or ampicillin.

Table 76-2 Agents Associated with Intrinsic and Acquired Antimicrobial Drug Resistance in Enterococci

Intrinsic Resistance
β-Lactams (particularly cephalosporins and penicillinase-resistant penicillins) Aminoglycosides (low concentrations) Clindamycin Fluoroquinolones Trimethoprim-sulfamethoxazole
Acquired Resistance
High concentrations of β-lactams, through alteration of penicillin binding proteins (PBPs) or production of β-lactamase Aminoglycosides (high concentrations) Glycopeptides (vancomycin, teicoplanin) Tetracycline Erythromycin Fluoroquinolones Rifampin Chloramphenicol Fusidic acid Nitrofurantoin
Gold HS, Moellering RC Jr. Antimicrobial drug resistance. *N Engl J Med*1996;335:1445–1453.

Acquired resistance: Acquired antimicrobial resistance among enterococci has been described for a number of agents including penicillins (includes organisms with and without β-lactamase), macrolides, tetracyclines, lincosamides, chloramphenicol, vancomycin, quinolones, quinupristin/dalfopristin, linezolid, and daptomycin. Aminoglycoside, β-lactam, and glycopeptide antimicrobials will be the focus of the following review of acquired resistance. All enterococci express some level of resistance (i.e., inherent resistance) to aminoglycosides based on failure of this class of agent to be actively transported into the cell. Notwithstanding, combinations of low concentration of penicillin and aminoglycosides are bactericidal for various strains of enterococci. The action of the penicillin on the cell wall renders entry of the aminoglycoside into the cell and allows it to act at the ribosomal site. Aminoglycosides fail to provide synergy with cell wall active agents for bactericidal activity if high-level resistance (minimum inhibitory concentration [MIC] greater than 2,000 µg/mL) is detected. High-level resistance among enterococcal strains renders aminoglycoside use futile, as these strains are not amenable to the synergistic effects of the aminoglycoside with penicillin.[1,43,44]

Although enterococci may appear susceptible to sulphonamides in vitro, they are able to circumvent the block in folate synthesis caused by sulphonamides, resulting in resistance to this class of antimicrobial agent in vivo. Most strains of enterococci have relatively high MICs for β-lactam agents, such as penicillins and cephalosporins.

Until the 1980s, ampicillin, a β-lactam agent, was a commonly used and effective antimicrobial for enterococcal infections. Since then, resistance to ampicillin has been increasing among *E. faecalis*and *E. faecium*. Ampicillin resistance can occur by either one of two mechanisms. The more prevalent mechanism, occurring most often in *E. faecium*isolates, is a decreased affinity of the penicillin-binding proteins for the β-lactam agent, resulting in high-level ampicillin resistance.[45]Alternatively, ampicillin resistance can occur from β-lactamase production from genes located in the chromosome or transferable plasmids.[46,47,48]Susceptibility testing with ampicillin is often used to predict susceptibility to amoxicillin, amoxicillin-clavulanic acid, ampicillin-sulbactam, piperacillin, and piperacillin-tazobactam among non-β-lactamase-producing enterococci.[2]In addition, susceptibility to ampicillin can be used to predict the susceptibility of *E. faecalis*to imipenem.[49,50]Of note, however, is the fact that susceptibility of enterococci to penicillin cannot be predicted by the susceptibility to ampicillin.

VRE epidemiology: Vancomycin and teicoplanin are glycopeptides with similar properties. They work by inhibiting cell wall synthesis in Gram-positive bacteria by binding with two D-alanine substrates. The cross-linking enzyme responsible for cell wall synthesis cannot then work properly, preventing cell wall synthesis. In resistant isolates, one of the two D-alanine substrates is replaced with D-lactate. This does not allow for vancomycin to bind properly, enabling cross-linking to progress. As of this writing, teicoplanin is available for patients in Europe only, not in the United States. Current MIC benchmarks for susceptibility and resistance to vancomycin among enterococci isolates have been set by the Clinical and Laboratory Standards Institute as follows: vancomycin-susceptible, MIC less than 4 µg/mL; intermediate resistance, MIC of 8 to 16 µg/mL; and vancomycin-resistant, MIC of at least 32 µg/mL.[51]

Table 76-3 Glycopeptide Resistance Genes Among

Gene	Location of *van*genes	Type of expression	Characteristics
*van*A	Plasmid; chromosome genes carried on conjugative transposon (Tn1546)	Inducible	High-level resistance to both vancomycin (MIC, 64 to 1,000 µg/mL) and teicoplanin (MIC, 16 to 512 µg/mL) Identified in *E. faecium*,*E. faecalis*,*E. avium*,*E. casseliflavus*,*E. durans*, *E. gallinarum*,*E. hirae*,*E. mundtii*, *E. raffinosus*,*E. sanguinicola*
*van*B	Plasmid; chromosome transferred by conjugation	Inducible	Acquired inducible resistance to various concentrations of vancomycin (MIC, 4 to 1,000 µg/mL) but remains susceptible to teicoplanin (MIC, 0.5 to 1 µg/mL) Identified in *E. faecium*and *E. faecalis*,*E. durans*,*E gallinarum*
*van*C	Chromosome	Constitutive	Intrinsic, constitutive, low-level resistance to vancomycin (MIC, 2 to 32 µg/mL) but remains susceptible to teicoplanin (MIC, 0.5 to 1 µg/mL). Identified in *E. gallinarum* and*E. casseliflavus*,*E. flavescens*
*van*D	Chromosome	Constitutive	Constitutive resistance to vancomycin and low levels of teicoplanin Identified in *E. faecium*,*E. faecalis*,*E. avium*,*E. gallinarum*,*E. raffinosus*
*van*E	Chromosome	Inducible	Identified in *E. faecalis*
*van*G	Chromosome transferred by conjugation	Inducible	Identified in *E. faecalis*

*Van*L	Unknown	Unknown	Low-level resistance to vancomycin; susceptible to teicoplanin Identified in E. *faecalis*

In 1988, the first isolates of vancomycin-resistant *E. faecalis*and *E. faecium*were reported in the United Kingdom and France.[52,53]Shortly thereafter, in 1989, similar resistant strains emerged in the United States.[18,39,54]Subsequently, VRE spread rapidly throughout healthcare facilities across Europe and the United States.[55,56]In Europe, VRE isolates were also identified in animal and community reservoirs.[15,16,17,26,52]The first report of VRE outside the healthcare setting was from sewage treatment plants.[15,57]VRE have also been recovered from livestock feces, uncooked chicken meat, and persons who work at farms or processing plants.[15,16,17,26,52,58,59]Epidemiological studies in Europe have shown an association between subtherapeutic doses of avoparcin, a growth-promoting glycopeptide antibiotic used in animal husbandry, and VRE recovery from animals reared for food.[26,59,60,61]In contrast, avoparcin use in animal husbandry in the U.S. is prohibited.[17]A little over a decade ago, the CDC established that a large proportion of chickens sold in U.S. supermarkets were contaminated by quinupristin-dalfopristin-resistant *E. faecium*.[62]However, the low prevalence and low level of resistance of the strains of *E. faecium*isolated from human stool specimens suggested that the use of virginiamycin in animals had not yet had a substantial influence in the United States.[62]

There are three key mechanisms of vancomycin resistance among *E. faecalis*and *E. faecium*: transferability of resistance through chromosomal exchange; expression of latent resistant genes leading to intrinsic resistance; and resistance acquired through the mobility of resistance genes on plasmids and/or transposons via conjugation, transduction, or transformation. At least seven reported phenotypes (*van*A through *van*L) of vancomycin resistance have been ascertained or characterized; subtypes exist within each major group as well: *van*B1-3, *van*C1-4, *van*D1-5, and *van*G1-2.[2]The characteristics of the most common phenotypes are outlined in Table 76-3. Enterococci that acquire the *van*A phenotype are highly resistant to vancomycin and teicoplanin. Antimicrobial drug resistance does not necessarily imply greater virulence among enterococcal isolates. Some studies have shown that crude mortality rates among patients with *E. faecium*bacteremia were not significantly different for patients with vancomycin-susceptible isolates versus and vancomycin-resistant isolates when adjustments were made for severity of illness.[10,11]

Diagnostic Microbiology

Detection and identification of enterococci is generally straightforward in the clinical microbiology laboratory. Once presumptive phenotypic characterization (catalase-negative, PYR-positive, LAP-positive, Gram-positive cocci that grow in 6.5 percent sodium chloride at 45°C) has been carried out, the species can be differentiated based on acid formation in mannitol and sorbose broths and hydrolysis of arginine.[63]Selective media, such as colistin-nalidixic acid agar (CNA), are available and assist in isolation (hemolysis can be read directly from the CNA plates). There are several commercial, automated systems now available for the identification of *Enterococcus*species.[2]Most of these systems are reliable for the identification of *E. faecalis*and *E. faecium*. A variety of molecular methods (e.g., DNA-DNA

hybridization, 16S rRNA gene sequencing, and polymerase chain reactin [PCR]) are now available in reference and various medical microbiology laboratories, enabling rapid identification and typing of isolates. However, there are no convincing data that availability of these techniques for the rapid identification of enterococci in routine clinical specimens (e.g., blood, wound, or urine cultures) results in more favorable patient outcomes. That said, molecular typing will, of course, continue to play an important, albeit adjunct, role in the characterization of outbreaks, epidemiologic and microbiologic research, taxonomy, and surveillance of HAIs and antimicrobial resistance associated with *Enterococcus*species.

In screening clinical specimens for VRE, one validated method is rapid phenotypic characterization, which can be achieved by growth on bile esculin azide agar (BEAA agar) with vancomycin 6 µg/mL (Remel, KS) followed by a subculture with a 30-µg vancomycin disk for phenotypic analysis. This method distinguishes *van*A and *Van*B strains from *van*C strains within 24 hours based on the vancomycin growth-inhibition zone. Specifically, *van*A and *van*B fail to produce inhibition zones of more than 6 mm, whereas *van*C isolates tend to produce inhibition zones 15 mm or more. Results falling within the 6- to 15-mm zone require further analysis. This differentiation is significant because *van*C isolates have low-level resistance and do not present the treatment problems of *van*A and *van*B strains.[64]Other methods used to identify vancomycin resistance in enterococci include automated systems, such as Vitek and conventional MicroScan systems.[65,66,67]Further characterization of isolates involves the identification of resistance genes by PCR, repetitive PCR, or characterization by pulse field gel electrophoresis (PFGE).[68,69]Molecular strain typing by these methods is useful in identifying horizontal transmission as well as assisting in the conduct and control of HAI outbreaks.

Infection & Disease Versus Colonization

Colonization is the presence of a microorganism in or on a host, with growth and multiplication, but without any overt clinical expression or detected immune reaction in the host at the time the microorganism is isolated. In a colonized patient, VRE may establish itself as part of a patient's flora in multiple or specific anatomic sites. For example, VRE colonize the gastrointestinal tract and can be found on the skin due to fecal shedding or in decubitus ulcers. Colonization with VRE generally precedes infection, but not all patients with colonization become infected. Persons either colonized or infected with VRE can serve as sources for secondary transmission. Enteric VRE colonization is typically asymptomatic and not associated with either diarrhea or constipation. Various risk factors have been associated with VRE colonization or infection (Table 76-4).

Table 76-4 Risk Factors Associated with

Risk Category	Specific Risk

Host	Age
	Immunocompromised
	Higher severity of illness
	Enteral feedings
	Burns
	Chronic renal failure
	Malignancy
	Neutropenia
Specific exposures	Inpatient in the intensive care unit (ICU)
	Prior exposure to vancomycin, third-generation cephalosporins, or antianaerobic agents
	Invasive procedures
	Surgical re-exploration
	Enteral tube feedings
	Contaminated medical equipment
	Prolonged hospital or ICU stay
	Prolonged antimicrobial therapy or preceding therapy
	Proximity to a previously known patient with VRE colonization or infection
	Exposure to a healthcare personnel assigned to another VRE patient
	Intrahospital transfer
	Colonization pressure
	Sucralfate
	Hemodialysis
	Transfer from long-term care facility

Risk factors for VRE colonization or infection include prolonged length of hospital stay, use of broad-spectrum antibiotics, having an indwelling invasive device, or close proximity to another patient colonized or infected by VRE.[18,70,71] The associated rise in environmental colonization pressure is now considered the major reservoir for infection and transmission.[12,72,73] Colonization pressure has been defined as the proportion of other patients colonized within a defined population or geographical unit.[12,19] Although acquisition of VRE is affected by colonization pressure, antimicrobial use, or enteral feeding, the effects of the latter two risk factors are more significant when colonization pressure is less than 50 percent; when the colonization pressure is greater than 50 percent, antimicrobial use and enteral feeding appear to have no effect on VRE acquisition.[12] Distinguishing between enterococcal contamination, colonization, and infection can be difficult but is very important if judicious use of antimicrobials is to be instituted in healthcare facilities. Thus, careful clinical assessment and interpretation of cultures that yield growth of enterococci is essential to avoid unnecessary and potentially harmful antimicrobial therapy.

Clinical Disease Management And Therapy

Enterococci are more likely to cause disease in immunocompromised or debilitated patients in the ICU setting or surgical ward. Affected patients are more likely to have comorbidities such as chronic heart or renal failure, liver cirrhosis, or diabetes; have one or more in situ invasive devices; or be undergoing treatment with broad-spectrum antimicrobials. That enterococci can colonize or infect patients who receive antimicrobial therapy for unrelated nonenterococcal infections adds to the complexity of enterococcal infection pathogenesis and treatment. The majority of patients with serious VRE infections also have enteric colonization with VRE. The fact that no single agent is entirely bactericidal against enterococci, compounded by the emergence of multidrug resistance to several classes of agents among VRE isolates, underlie the reality that enterococcal infections can be extremely difficult to treat and is one of the reasons that management of deep or systemic enterococcal infections in susceptible hosts often requires combination antimicrobial therapy.[18,43]

Enterococci are important causes of BSIs, endocarditis, urinary tract infections, meningitis, and SSIs. Urinary tract infections, generally, do not require bactericidal therapy; monotherapy is sufficient. For invasive infections such as BSIs, endocarditis, meningitis, or intra-abdominal sepsis, a therapeutic regimen with bactericidal activity is indicated. For patients with enterococcal infections, treatment options are contingent on the susceptibility profile of the clinical isolate and whether the infection is superficial, deep, or systemic. Determining the therapeutic regimen and duration of treatment may require the expertise of an infectious diseases consultant. Because of the inherent properties that reduce the affinity of their penicillin-binding proteins for β-lactams, all enterococci require 4 to 16 μg/mL of penicillin for inhibition. This inherent penicillin resistance is enhanced with β-lactamase-producing strains of enterococci, especially *E. faecalis.*However, for infections caused by susceptible isolates, ampicillin or penicillin are the indicated cell wall agents. *Enterococcus*species are resistant to all cephalosporins and most are resistant to oxacillin, nafcillin, streptomycin, and erythromycin. Isolates should be tested routinely for susceptibility to penicillin, ampicillin, vancomycin, quinupristin/dalfopristin, and linezolid.

AGENTS WITH ACTIVITY AGAINST VRE

Quinupristin/dalfopristin (a mixture of streptogramin agents) was developed in the late 1980s and has been approved by the U.S. Food and Drug Administration (FDA) for the intravenous treatment of *E. faecium*infections.[74]The FDA has not approved quinupristin/dalfopristin for *E. faecalis*infections because resistance to this agent has been detected consistently in *E. faecalis*isolates.[75,76,77]A growing body of literature has documented treatment success against VRE infections.[78,79]However, quinupristin/dalfopristin is limited by its lack of activity against vancomycin-resistant *E. faecalis*and its musculoskeletal side effects (myalgia and arthralgia).[79]

Linezolid is a synthetic oxazolidinone agent that binds to the 50S ribosome and inhibits the initiation of protein synthesis.[80]It is available in intravenous and oral preparations and has bacteriostatic activity against VRE isolates. Side effects include thrombocytopenia, leucopenia, peripheral neuropathy, lactic acidosis, and raised hepatic enzyme levels. Some studies have documented efficacy in the treatment of VRE infections, though there are reports of acquired resistance in some VRE isolates.[81,82,83]

Daptomycin is a large cyclic lipopeptide that binds to bacterial membranes and causes rapid depolarization of membrane potential.[84]Although its action is bactericidal against VRE, it has been approved by the FDA for treatment of complicated skin and soft tissue infections caused by susceptible

strains, not for treating VRE infections. Side effects include myalgias, weakness, raised creatine phosphokinase, neuropathy, and significant myopathy. Thus, creatine kinase levels should therefore be checked before commencing therapy with this agent. Daptomycin should be discontinued in patients who are symptomatic and have creatine kinase levels greater than five times the upper limit of normal or, in asymptomatic patients, an increase of greater than 10 times the upper limit of normal. Daptomycin resistance among *E. faecalis*isolates has been reported.[85]

Tigecycline is a glycylcycline agent derived from minocycline.[86,87]It is bacteriostatic and has a broad spectrum of activity against growth of resistant Gram-positive and Gram-negative pathogens. Currently, it is approved only for complicated skin and skin structure infections and intra-abdominal infections, including those caused by vancomycin-susceptible *E. faecalis*. At present, tigecycline does not have FDA approval for infections caused by *E. faecium*and VRE.[86]

Chloramphenicol inhibits bacterial protein synthesis and is bacteriostatic for most bacterial pathogens. Use in the United States has been limited due to unavailability of an oral preparation and its potential for bone marrow toxicity. Although it has demonstrated activity against some strains of enterococci, no significant effect of its use on mortality could be demonstrated.[88]Chloramphenicol resistance among European and U.S. enterococcal isolates is increasing.[5,89]

Telavancin is a lipoglycopeptide that has bactericidal activity against various Gram-positive microorganisms, including *Enterococcus*spp. It has been approved by the FDA for treatment of complicated skin infections caused by vancomycin-susceptible *E. faecalis*; however, it has not been approved by the FDA for the treatment of VRE infections. Although the in vitro activity of telavancin against *Enterococcus*is very good, there is a paucity of published outcome data regarding the utility of using this agent for enterococcal infections.

ENTEROCOCCAL BLOODSTREAM INFECTIONS

Risk factors associated with enterococcal BSIs include intrinsic factors linked to the patient (host) and extrinsic factors linked to the environment, practices, and procedures, therapies, and device use (Table 76-4). Enterococcal BSIs are either primary (direct entry into the bloodstream from the gastrointestinal tract or an intravascular device) or secondary to concomitant infection at another anatomic site (e.g., urinary tract or burn sites, respiratory tract).[90,91,92,93]More recent data indicate that among patients colonized with VRE, approximately 4 percent develop VRE BSIs due to a related strain.[71]Independent risk factors for BSIs among colonized patients include admission from a long-term care facility, infection of an additional body site, or exposure to vancomycin.[71]

The diagnosis of a BSI (nonendocarditis) is based mainly on at least two sets of blood cultures positive for enterococcal growth but, not uncommonly, is made on the basis of a single positive blood culture. The subsequent decision to initiate therapy should be made within the context of symptoms and clinical signs, the presence of at least one indwelling intravascular devices, culture results from other anatomic sites, and deciding whether the infection is primary or secondary. Most patients would be expected to be started on empiric antimicrobial therapy, which can be tailored after results of antimicrobial susceptibility testing become available or discontinued after 1 to 2 weeks of therapy. For bacteremia in the absence of native-valve endocarditis, a prosthetic valve, or history of intravenous drug abuse, it remains unclear whether monotherapy with a single β-lactam agent is better than combination therapy by the addition of gentamicin.[94,95,96,97]The agent of choice for monotherapy is ampicillin if the enterococcal strain is

susceptible, vancomycin if there is β-lactam resistance or allergy, and ampicillin/sulbactam (or amoxicillin/clavulanate) if strain is a β-lactamase producer. For nonendocarditis VRE BSIs in the absence of β-lactam resistance, combination therapy with ampicillin and gentamicin should be considered. When strains exhibit both vancomycin and β-lactam resistance, newer agents such as linezolid or quinupristin/dalfopristin (*E. faecium*only) have to be considered. In summary, traditional antimicrobial treatment for ampicillin- and glycopeptide-susceptible enterococcal infection remains a penicillin-, ampicillin-, semisynthetic penicillin-based regimen, or vancomycin in a penicillin-intolerant individual. The need for a bactericidal combination with a cell wall-active agent combined with an aminoglycoside is most supported for native or prosthetic valve endocarditis but is unproven for the majority of infections caused by enterococci.[29,83]

Endocarditis: Enterococcal endocarditis is no longer a unimicrobial, community-acquired disease of Caucasian men.[98]Other data suggest that the presence of a prosthetic valve and infection by *E. faecalis*are associated with an increased risk for endocarditis.[98]At the same time, however, most cases of enterococcal BSIs are not associated with endocarditis.[42,98,99,100]For patients with enterococcal endocarditis, treatment options are contingent on the susceptibility profile of the isolate. Specific antimicrobial therapy must be aggressive, using bactericidal rather than bacteriostatic agents. Antimicrobial susceptibility studies should be carried out for penicillin, ampicillin, vancomycin, quinupristin/dalfopristin, and linezolid. The isolate must be tested for β-lactamase production and for high-level resistance to gentamicin and streptomycin. If high-level resistance is ascertained for the latter two agents, aminoglycosides should not be administered singly or in combination therapy. Treatment may involve a single agent if the isolate is highly susceptible in vitro; combination therapy is suggested if synergism is possible. Treatment is prolonged, usually 4 to 6 weeks. Drug selection and duration of treatment should involve the expertise of an infectious diseases consultant.

For native or prosthetic valve endocarditis caused by *Enterococcus*species that are susceptible to penicillin, gentamicin, and vancomycin, choices of therapeutic regimens include ampicillin plus gentamicin for 4 to 6 weeks or penicillin plus gentamicin for 4 to 6 weeks. If the patient is penicillin intolerant, vancomycin plus gentamicin is an alternative therapeutic regimen. For intrinsic penicillin resistance, vancomycin plus gentamicin is the combination of choice. For endocarditis caused by β-lactamase-producing, vancomycin-susceptible enterococci, ampicillin-sulbactam plus gentamicin or vancomycin plus gentamicin are indicated. Finally, for endocarditis caused by enterococci that are resistant to penicillin, gentamicin, and vancomycin, an infectious disease consultation is recommended; choices of antimicrobials for this scenario include linezolid, quinupristin/dalfopristin, and imipenem. For more information, refer to the Infectious Diseases Society of America (IDSA) guidelines for the treatment of infective endocarditis.[101]

ENTEROCOCCAL URINARY TRACT INFECTION

Enterococci are a common cause of urinary tract infections (UTIs); most of these infections are healthcare-associated. Among healthy ambulatory patients, less than 5 percent of UTIs are caused by enterococci, compared to significantly higher rates among hospitalized patients. Risk factors for enterococcal UTI include urinary tract instrumentation, indwelling catheterization, genitourinary tract disease associated with obstruction, and prior antimicrobial exposures.[102,103]There are no clinical manifestations of enterococcal UTI that distinguish this etiologic agent from other urinary pathogens.

It is important to remember that the susceptibility profiles reported for urinary pathogens are breakpoint MICs related to blood concentrations of antimicrobial agents. The achievable concentrations of such

agents in the urine are usually many-fold higher than serum concentrations. Hence, "drug-resistant" enterococcal infections of the lower urinary tract often can be treated with conventional dosing of nitrofurantoin, ampicillin, amoxicillin, or fosfomycin.[104,105] Complicated UTIs may be associated with a greater severity of illness and risk of kidney damage; such infections require intravenous ampicillin or vancomycin therapy.

ENTEROCOCCAL CLOSED-SPACE INFECTIONS

Enterococci can cause intra-abdominal and pelvic abscesses, usually as part of a mixed (i.e., polymicrobial) infection following abdominal surgery or trauma.[106] More than a decade ago, the presence of enterococcus was recognized as an independent predictor of treatment failure in complicated intra-abdominal infections.[107] It was also recognized that antimicrobials that lack activity against *Enterococcus* can often be employed successfully in intra-abdominal infections, even when enterococci are present as part of the polymicrobial flora.[108] Although secondary enterococcal BSIs are not usual in patients with enterococcal intra-abdominal sepsis, breakthrough enterococcal septicemia may occur in an immunocompromised host and is associated with high mortality.[108] Intra-abdominal sepsis caused by enterococcal species have been quite problematic in liver transplant patients.[109,110]

For orthotopic liver transplant recipients, the source of VRE infection is often the gastrointestinal tract; in this patient population, VRE infection is an independent predictor of morbidity and mortality.[111]

VRE is now recognized as an emerging healthcare-associated pathogen that causes potentially fatal intra-abdominal infections in the postsurgical setting.[112] Enterococcal surgical site infections may be the source of secondary enterococcal BSIs. In uncomplicated intra-abdominal infection, the infectious process might involve just a single organ, and no anatomical disruption is present.[113] Generally, such infections can be treated with surgical resection alone with no antimicrobial therapy apart from perioperative prophylaxis.[113] In the majority of cases, wound healing will occur with routine wound management strategies. Management of complicated intra-abdominal sepsis includes standardized antimicrobial monotherapy or combination therapy.[113] For intra-abdominal infections, routine coverage against enterococci is not recommended but might be indicated for specific clinical conditions, such as the presence of septic shock in patients previously receiving prolonged treatment with cephalosporins, immunosuppressed patients at risk for bacteremia, patients with prosthetic heart valves, or a history of recurrent intra-abdominal infection complicated by severe sepsis.[113]

WOUND AND JOINT INFECTIONS

Enterococcus species are the third most common cause of SSIs in U.S. healthcare facilities.[36] In addition, *Enterococcus* is often implicated in cases of osteomyelitis and joint sepsis, including prosthetic joint infections. Treatment of these infections is contingent on the susceptibility of the implicated isolate. Osteomyelitis and joint infections require at least 4 to 6 weeks of parenteral therapy, which is often adjunct to surgical management. For patients with prosthetic joint infections who have actually completed a prolonged course of antimicrobial therapy, and in whom the original prosthesis remains in situ, long-term suppressive therapy might have to be considered.

ENTEROCOCCAL PNEUMONIA AND MENINGITIS

Enterococcal respiratory tract infections are rare events; in one occasional report, it was described as a complication of topical antimicrobial prophylaxis.[114]Enterococci are a rare cause of meningitis, occurring primarily in patients who have undergone neurosurgical procedures and persons with in situ intraventricular or intrathecal devices or ventriculoperitoneal shunts, a history of head trauma, and existing anatomic defects or congenital anomalies of the central nervous system.[115,116,117]Combination antimicrobial therapy is recommended for enterococcal meningitis.

STOOL COLONIZATION WITH *ENTEROCOCCUS*

Over the past decade, several studies have been published to elucidate the natural history and risk factors associated with enteric VRE colonization and to establish the utility of eradication. Two uncontrolled, short-term clinical studies suggested efficacy of oral bacitracin in the eradication of enteric VRE colonization.[118,119]However, two other studies using oral bacitracin therapy showed no significant difference in VRE eradication rates after a longer follow-up period.[120,121]Other studies using different antimicrobial interventions have also drawn different conclusions: 5 days of oral doxycycline and rifampin was successful in eradicating enterococcal carriage[122]; in contrast, oral bacitracin plus gentamicin did not reduce VRE colonization or bacteremia.[123]Of note, a substantial number (37 to 66 percent) of nontreated patients in these studies had spontaneous eradication of enteric VRE.

Control And Prevention Of Vre Infections

That endemic and epidemic HAIs are preventable has periodically been reaffirmed by milestone reports dating from as far back to Semmelweis, to the myriad studies published over the past two decades dealing with the unequivocal effect of hand washing with soap and water; proper care of urinary catheters, respirators, intravascular catheters, and surgical wounds; numerous evidence-based infection control guidelines published by the CDC; and position papers issued by the SHEA, the Association of Practitioners of Infection Control, and the IDSA.

The Hospital Infection Control Practices Advisory Committee (HICPAC) guidelines, aimed at preventing and controlling VRE transmission in healthcare settings, were published initially in 1995[124]and updated in 2007.[125]Although implementation of these guidelines following VRE outbreak investigations played no small part in the resolution of these outbreaks, there are still no published outcome studies to show how implementation of the HICPAC guidelines might have resulted in reducing rates of VRE infections in facilities across the nation.[126,127]Eradicating VRE from ICUs or other high-risk areas may be extremely difficult. However, the current HICPAC recommendations require resource-intensive efforts, including behavior modification and costly financial allocations.

The HICPAC guidelines stress that the prevention and control of vancomycin resistance will require a coordinated, concerted effort from various departments of a hospital and administrative support.[125]

HICPAC strongly encourages hospitals to develop their own institution-specific plans that address the following elements: (1) prudent, judicious vancomycin use by clinicians; (2) facility-wide, unit-targeted, and informal education of hospital personnel regarding vancomycin resistance, and hand hygiene in conjunction with other control measures; (3) early detection and prompt reporting of vancomycin resistance in enterococci and other Gram-positive microorganisms by the hospital microbiology laboratory to monitor trends and effectiveness of interventions; and (4) immediate implementation of

appropriate infection control measures to prevent person-to-person transmission of VRE.[124,125] The use or modification of these recommendations, as outlined for acute care settings, remains a challenge for extended care facilities, small hospitals, and home care settings.[128]

Numerous reports presented at the SHEA annual meetings over the past decade have repeatedly shown control of endemic or epidemic VRE infections through implementation of the SHEA guidelines with more emphasis on Contact Precautions and less on Standard Precautions. In fact, the CDC has not provided any evidence-based data showing that Standard Precautions and passive surveillance have actually started to control the spread and transmission of VRE.[129] The SHEA guidelines are based on identification and containment of spread through (1) active surveillance cultures to identify the reservoir for spread; (2) routine hand hygiene; (3) barrier precautions for patients known or suspected to be colonized or infected with VRE; (4) implementation of an antimicrobial stewardship program aimed particularly at reducing the overprescribing of vancomycin and cephalosporins; and (5) decolonization of colonized patients.[130] There is now growing evidence that active surveillance cultures reduce the incidence of VRE infections and that programs described in the SHEA guidelines are effective and cost effective.[129,131,132]

The SHEA and HICPAC guidelines are similar in that they both aim to improve patient outcomes through improvement of hand hygiene measures and enhancement of prescribing practices through an antimicrobial stewardship program. The key difference is the role of active surveillance cultures in each guideline: the SHEA guideline recommends more aggressive use of active surveillance cultures, whereas the HICPAC isolation guideline calls for individual facilities to assess their own needs and risks and to implement routine clinical cultures when a problem is ascertained.[133] The CDC has recommended Contact Precautions for preventing intrahospital transmission of important antimicrobial-resistant pathogens, including VRE. Various studies confirm that this approach works only when sufficient active-surveillance cultures are obtained to detect the reservoir for spread.[134,135] Active VRE surveillance involves prospective evaluation of patients to determine colonization pressure and transmission rates. Although abundant resources are required for active surveillance, it facilitates early detection and potential containment of VRE. In contrast, passive surveillance involves screening culture specimens obtained for other clinical reasons.

The role of scheduled rotation of antimicrobial agents in the prevention and control of VRE has been evaluated.[136] Sequential cycling of antimicrobials presumably reduces the selection pressure for the emergence of particular antimicrobial resistance genes for at least some infections.[137,138] However, the rotation of Gram-negative antimicrobial agents among ICU patients has not shown any reduction in rates of VRE acquisition. Currently, there are no data that have conclusively demonstrated reductions in rates of VRE infections through scheduled antimicrobial cycling.[138,139,140,141]

Finally, the issue of when to discontinue Contact Precautions remains a perennial issue and concern in acute care facilities. In fact, as stated in the HICPAC guidelines, there is a paucity of published data on when to discontinue Contact Precautions for patients colonized with VRE. According to these guidelines, in the context of an outbreak caused by VRE, Contact Precautions should be used indefinitely for all previously infected and known colonized patients.[125] The HICPAC guidelines go on to say that if active surveillance cultures are used to detect and isolate patients colonized with VRE, and there is no decolonization of these patients, it would be prudent to use Contact Precautions for the duration of the

stay in the setting where they were first implemented.[125] The HICPAC guidelines conclude that it is reasonable to discontinue Contact Precautions when three or more VRE surveillance cultures are repeatedly negative over the course of a week or two in a patient who has not received antimicrobial therapy for several weeks, especially in the absence of a draining wound, profuse respiratory secretions, or evidence implicating the specific patient in ongoing VRE transmission within the facility.[125] Likewise, HICPAC states that if active surveillance cultures are used to detect and isolate patients colonized with VRE, and there is no decolonization of these patients, it is logical to assume that Contact Precautions would be used for the duration of stay in the setting where they were first implemented.

Summary And Conclusions

Enterococcus species are members of normal human and animal gastrointestinal flora. They are extremely hardy and have been recovered from a variety of environmental surfaces and equipment in healthcare facilities; transmission via hands of HCP is common. Because of their intrinsic and acquired resistance to many antimicrobial agents, they remain an infection control concern and present significant therapeutic challenges. Active surveillance cultures for VRE in ICUs followed by isolation of colonized persons appears to be an effective strategy for VRE control in some institutions. Isolation purely on the basis of history of previous VRE detection, at least for VRE, appears to be of little benefit. Standard Precautions and isolation of the occasional patient recognized to be colonized through routine clinical cultures have not proved effective in reducing rates of VRE infections.

Future Trends & Research

Enormous challenges remain for controlling transmission of healthcare-associated pathogens in acute care facilities and conducting similar evaluations and strategies in long-term care facilities and the home care setting. These challenges include development of uniform surveillance definitions and protocols and a nonpunitive reporting system for HAIs in long-term care facilities and home care; identification of high-risk infections (e.g., bloodstream, pneumonia, or wounds) that need to be focused on in these settings; and determination of relevant numerators and denominators for calculating device-specific rates for infections in these settings. These challenges are likely to be tempered by the fact that by focusing on specific, albeit high-risk, infections, the true magnitude and epidemiology of VRE transmission in the home and long-term care facilities will likely remain unknown or uncharacterized for some time to come. The onus is now on healthcare professionals and healthcare administrators to invest intelligently in infection prevention and control programs, to enhance existing surveillance activities in targeted areas, and to avoid regarding death and morbidity as inevitable. Hospital epidemiologists and the CDC also have a responsibility to evaluate the effectiveness and cost benefit of the programs described in the SHEA guidelines for the control of VRE transmission in the acute care facilities.

APIC TEXT OF INFECTION CONTROL AND EPIDEMIOLOGY

Environmental Gram-Negative Bacilli

Published: October 15, 2014

Abstract

Pseudomonas*spp.,* Acinetobacter*spp., and other glucose nonfermentative bacilli are common causes of healthcare-associated infections. These ubiquitous pathogens contribute to a wide variety of clinical syndromes and are particularly notable for their intrinsic antimicrobial resistance.* Pseudomonas*spp. originally gained notoriety under the outdated terms "nosocomial" or "hospital-acquired" pathogens over a 40-year time frame; they continue to afflict patients in a variety of healthcare settings. Acinetobacter infections have played an increasingly prominent role, mainly in hospital outbreaks and in endemic infections. A host of other nonfermentative bacilli also can result in outbreaks when infection prevention measures are not followed.*

Key Concepts

- Microbiologic characterization of important glucose nonfermentative Gram-negative bacilli.
- Review of major clinical syndromes.
- Treatment and management of infections associated with nonfermentative bacilli.
- Principles used to prevent and control healthcare-associated nonfermentative bacilli and their reservoirs.

Background

Arising primarily from an aquatic background, the ubiquitous nonfermentative Gram-negative bacilli have minimal growth requirements and cause a wide array of opportunistic infections. These organisms have many reservoirs within hospitals and other healthcare settings and are frequently resistant to commonly used antibiotics. *Pseudomonas aeruginosa*gained notoriety as a threat in the 1960s as streptococcal and

staphylococcal infections were eclipsed by aerobic Gram-negative bacilli as causes of bacteremia.[1]

Acinetobacter spp. are now recognized as important pathogens that cause difficult-to-treat infections, particularly in compromised hosts and military personnel, due to the organism's inherent properties of antimicrobial resistance. Strains of *Acinetobacter baumannii* completely resistant to usual antimicrobial agents have been reported.[2,3]*Acinetobacter*spp. cause a significant percentage of endemic infections and several reported epidemics each year.[4]Some of these reports reflect an interest in improving typing methods for use in epidemic investigations, but other reports emphasize epidemics in specialized settings, such as *Acinetobacter*infections in neonatology units or military field hospitals.[4,5,6,7,8,9,10]

Basic Principles

A basic principle in the prevention of infection with any of these organisms is to minimize endogenous and exogenous sources of acquisition. Careful studies have suggested that 2.6 to 24 percent of patients admitted to the hospital carry *P. aeruginosa*in their stool, and infection with these strains has been documented.[11,12,13]These cases usually are "secondarily endogenous" (colonization occurs while in the hospital but prior to infection) or related to cross-transmission.[14]One study estimated the incidence of *P. aeruginosa*infections as high as 60 percent, but this varies with the presence of environmental reservoirs and healthcare personnel infection prevention practices.[15]Less clear is the role of the architectural environment.[16]

ONGOING TRENDS

The incidence of Gram-negative bacteremia continued to increase into the 1970s, although subsequently Gram-positive pathogens and *Candida*spp. played an increasingly important role.[17]*P. aeruginosa*continues to be an important cause of healthcare-associated bacteremia, although its percentage of contribution to all bacteremias varies widely from hospital to hospital.[17]Non-*aeruginosa*pseudomonads and *Acinetobacter*spp. have also become increasingly important as causes of bacteremia, causing as many as 13 percent of bloodstream infections at some institutions.[17]Intravenous catheter-associated infections are caused by *P. aeruginosa*in 3 to 6 percent and *Acinetobacter*spp. in 1 to 2 percent of cases.[18]Enterobacteriaceae are the most common pathogens resulting in urinary tract infections in hospitalized patients, but *P. aeruginosa*is the third most common cause overall.[11]Other NFB are important causes, particularly with prolonged catheterization. *P. aeruginosa*is second only to *Staphylococcus aureus*as a cause of burn infections. Generally, *P. aeruginosa*causes less than 10 percent of surgical site infections.[19]Aerobic Gram-negative bacilli generally cause more than 60 percent of healthcare-associated pneumonias.[20,21]

PRACTICE-SPECIFIC TRENDS

Although this chapter focuses primarily on intensive care unit (ICU) and general ward-related infections, nonfermentative bacilli (NFB) are important pathogens in other settings, such as nursing homes. *P. aeruginosa*is an important pathogen in severe pneumonias in institutionalized older people.[22]

Microbiologic surveillance of nursing home residents has identified *P. aeruginosa*as a primary isolate in a

patient population that is frequently treated with antimicrobial agents.[23]Recommendations for controlling antimicrobial resistance in long-term care facilities have been proposed by a task force of the Society for Healthcare Epidemiology of America (SHEA).[24]

INTERNATIONAL TRENDS

NFB have been widely reported as hospital pathogens around the globe. An outbreak in a neonatal ICU in India resulted in 68 strains of *A. baumannii*from the blood and cerebrospinal fluid of neonates during a 6-month period.[25]NFB have been reported as important hospital pathogens in Brazil, the United Kingdom, Spain, Turkey, Israel, and many other countries. Disaster-related NFB infections were reported after the 2004 Southeast Asian tsunami.[26]

EPIDEMIOLOGY AND INFECTIOUS AGENTS

Members of the genus *Pseudomonas* are aerobic, motile, Gram-negative bacilli commonly found in moist environments.[27]They constitute the most common healthcare-associated pathogens among the NFBs. This grouping has undergone changes in nomenclature, and several organisms once characterized within the*Pseudomonas* genus have been reclassified. These include *Acinetobacter, Alcaligenes, Stenotrophomonas, Flavobacterium, Sphingomonas, Flavimonas, Chryseobacterium, Comamonas, Burkholderia*, and others.[28]*Pseudomonas*spp. are catalase-positive, use oxidative rather than fermentative pathways to obtain energy from carbohydrates, and are usually oxidase-positive. *P. aeruginosa*is the most important and frequently isolated pathogen within this genus.[27]

Members of the genus *Acinetobacter*are generally encapsulated, nonmotile, aerobic Gram-negative bacilli that may appear coccoid in their stationary growth phase.[29]They are oxidase-negative, nonnitrate reducing, unable to ferment glucose, and lack color.[30]In fact, this paucity of distinctive characteristics previously resulted in frequent misidentification and subsequently has contributed to a number of taxonomic revisions.[29]The taxonomy of *Acinetobacter*spp. is complex, with 25 DNA homology groups and multiple named species.[31]The most clinically important are sometimes grouped together as *A. calcoaceticus-A. baumannii*complex.[4]

Stenotrophomonas maltophilia (formerly classified as *Xanthomonas maltophilia*) is a motile Gram-negative aerobic bacillus that differs from*P. aeruginosa*by generally being oxidase-negative, although a few strains are weakly oxidase-positive.[28]Occasionally, *S. maltophilia*can be confused with *Burkholderia cepacia*.[32]A variety of other glucose nonfermenters can be clinically significant, including *Alcaligenes, Chryseomonas, Comamonas, Flavimonas,* Gilardirod group 1, *Myroides, Ochrobactrum, Oligella, Ralstonia, Rhizobium, Shewanella*, and *Weeksella*.[30,31,33,34]

OCCURRENCE AND RESERVOIRS

The vast majority of the organisms discussed in this chapter are well adapted to proliferating in relatively pure water.[11,28,35]This is particularly true for the pseudomonads*, Flavobacterium,*and *Acinetobacter*. This accounts for the slang term "waterbugs" that is often used in referring to these organisms.

Environmental Gram-Negative Bacilli

ACINETOBACTER

Most epidemics have involved respiratory tract infections. Because these organisms are widely distributed in water sources, it is not surprising that many outbreaks have been associated with pressure transducers, humidifiers, ventilators, and other respiratory therapy equipment, including a manual weaning criteria machine.[9,35,36]More than one outbreak has been linked to contaminated mattresses.[37, 38]*Acinetobacter*is notable for its ability to persist in the environment with survival on dry inanimate surfaces for about a month.[39]Infected and colonized patients may distribute the organism widely. In one report, environmental cultures following a patient's discharge documented the organism on side room walls, floors, and at least 13 other different types of horizontal surfaces in and near his room. Curtains have been culture positive for as long as 13 days after patient discharge.[40]

Outbreaks have implicated the role of hydrotherapy of burn patients, hand transmission in the surgical ICU, contaminated irrigation tubing in a burn unit, and contaminated endoscopes for biliary or upper gastrointestinal tract procedures.[10,41,42,43,44,45,46]These supplement the other commonly reported sources of sinks, respiratory therapy equipment, disinfectants, and distilled and other water supplies.[12,15,47,48]Food is a potential source of a number of Gram-negative bacilli.[11,48]Tomatoes are a classic source of *P. aeruginosa*. *Acinetobacter*spp. can be isolated from a host of foods and as a contaminant of human milk.[47,48]For this reason, special diets have been advocated for granulocytopenic patients.

Enteral feedings and oral solutions can become contaminated with a variety of organisms, including *Pseudomonas*spp., *Acinetobacter*spp., and other NFB.[49,50]*Acinetobacter*spp. are one of only a few Gram-negative organisms that can routinely reside on healthy, dry human skin.[29]One survey in New York identified *A. baumannii*on the hands of 10 percent of community residents.[51]

PSEUDOMONAS

P. aeruginosa, the most virulent member of this group of organisms, is a classic healthcare-associated pathogen and the most frequently isolated of all the organisms discussed in this chapter. It is particularly dreaded as a cause of sepsis and ecthyma gangrenosum in the neutropenic host and as the cause of malignant external otitis in patients with diabetes mellitus. Burn infections, endocarditis, meningitis, gastrointestinal tract, eye, and musculoskeletal infections are also well described.[11]Its numerous virulence factors, ability to survive in moist environments, growth with minimal nutritional requirements, tolerance for a variety of temperatures, and innate antibiotic resistance all contribute to its success in causing healthcare-associated infections (HAIs).[11]

Essentially, whenever a moist environment is present with a patient having absent or circumvented host defenses, the possibility of pseudomonal infection is real. Outbreaks in the past have identified other reservoirs, including orthopedic plaster, transvenous pacemakers, operating room suction apparatus, and mattresses.[11]Cockroaches have also been suggested as possible vectors.[52]Bowel colonization of patients is important for *P. aeruginosa*.[11,12,13,15]Stool cultures are generally more sensitive than are rectal swabs in detecting colonization.[13]Infected patients are an important reservoir for essentially all Gram-negative

pathogens. Respiratory tract infection or colonization, wound infections, and infected urine are all important sources of bacteria and may result in substantial environmental contamination, in addition to seeding the hands of healthcare personnel.[15,30,41] A reported *P. aeruginosa* meningitis outbreak was associated with the rinsing of spinal needles with contaminated saline.[53] Nontransient carriage of Gram-negative bacilli on the hands of healthcare personnel has been noted.[54] Disinfectants and various germicides may become contaminated with numerous types of NFB, including *Pseudomonas* spp., *S. maltophilia, Flavobacterium meningosepticum, Alcaligenes faecalis*, and *Alcaligenes xylosoxidans*.[55]

Essentially, any wet healthcare environment, including ice machines, multidose vials, and tap water, can serve as a reservoir once contaminated. Flowers frequently harbor indigenous, multiresistant Gram-negative bacilli, including NFB.[56]

STENOTROPHOMONAS MALTOPHILIA AND *BURKHOLDERIA CEPACIA*

S. maltophilia and *B. cepacia* can be found in water, soil, plants, animal sources, and decaying organic materials. Both organisms have been widely identified from many sources within the hospital setting, including tap and distilled water, thermometers, contaminated disinfectants, dialysis fluids, catheters, and ventilator temperature sensors.[32]

Mechanisms of Transmission

Convincing demonstration of the transmission of Gram-negative bacilli through the air has been extremely rare. *P. aeruginosa* and other Gram-negative bacilli were linked to healthcare-associated bacteremias that occurred after the introduction of a novel chute-hydropulping waste disposal system in a 16-story hospital.[57] One report has implicated airborne transmission of *A. baumannii* on the basis of settle plate cultures and contamination of adjacent bedding, but other routes of transmission were not able to be excluded.[40,58]

Contamination may occur during the manufacture, distribution, or administration of many products used in healthcare delivery. Generally, the offending organism must be able to proliferate in the contaminated product to reach levels that result in clinical symptoms. For *P. aeruginosa* this has included a variety of solutions and antiseptics. For *P. putida* and *P. fluorescens* this also includes blood and blood by-products. *Alcaligenes xylosoxidans* has been associated with contaminated dialysate, chlorhexidine, and respiratory equipment. *Chryseobacterium meningosepticum* has been associated with contaminated ice, water, and humidifiers.[59] Endoscopes, which are difficult to disinfect, and automated endoscope reprocessors can serve as reservoirs for NFB.[7,60] *Comamonas* spp. infections have been associated with exposure to tropical fish tanks and endogenous infection from the gastrointestinal tract such as appendicitis.

INCUBATION

The concept of an incubation period is not as useful in evaluating HAI outbreaks or epidemics for NFB as for many other pathogens because infection may result from colonization that happened either recently or remotely.

Clinical Features

The NFBs produce a large variety of clinical syndromes in both normal and compromised hosts because of their virulence factors. The most common clinical scenarios are urinary tract infections; respiratory tract infections, particularly in ICU patients; primary and secondary bloodstream infections; and wound infections.[34]*Acinetobacter*spp. have been reported to cause suppuration in any organ system but particularly as a pathogen in ventilator-associated pneumonia, meningitis, urinary tract infection, peritonitis, endocarditis, and soft tissue infections.[7,29,30,61]Some reports regarding these organisms demonstrate seasonal variation with a peak in the summer.[4]Thus, endogenous infections and seasonal variation may obscure the onset of an outbreak.

Burkholderia cepacia(formerly*Pseudomonas cepacia*) is most frequently noted as a cause of respiratory tract infections in patients with cystic fibrosis.[62,63]Persistent infection has been associated with worsening pulmonary function and increased mortality.[64]Three distinct clinical patterns exist: (1) chronic asymptomatic carriage, (2) progressive deterioration, and (3) rapid, often fatal deterioration in previously mildly affected patents with necrotizing pneumonia and bacteremia.[32]*B. cepacia*pneumonia may cause cavitation in nearly 30 percent of patients.[65]

In patients without cystic fibrosis*B. cepacia*, infections are almost all healthcare-associated or related to intravenous drug abuse. Outbreaks have been related to intra-aortic balloon pumps, contaminated water sources, respiratory therapy equipment such as reusable electronic ventilator temperature probes, or contaminated disinfectants (classically from "topping" off bottles of the disinfectant).[66,67,68]Even a single significant HAI with *B. cepacia*may warrant investigation, but this organism may also cause pseudoepidemics.[69,70]

Ralstonia pickettii(formerly *Pseudomonas pickettii* and*Burkholderia pickettii*) has been responsible for epidemics of bloodstream infections associated with contaminated distilled or "sterile" water. Contamination may occur by manufacturers or less commonly be related to narcotic tampering.[71,72] Indwelling intravenous catheter infections have also been reported.[73]

Stenotrophomonas maltophilia has been reported to cause abscesses, meningitis, endocarditis, conjunctivitis, wound infections, urinary tract infections, and pneumonia.[74]The resistance of *S. maltophilia*to aminoglycosides, imipenem, and many cephalosporins is more notable than the production of any unique clinical syndrome. Outbreak investigations have implicated respiratory therapy or monitoring equipment, contaminated disinfectants, and ice machines.[17,55,75]

*Agrobacterium tumefaciens*has been implicated in HAIs, including urinary tract infections, peritonitis, wound infections, prosthetic valve endocarditis, and sepsis.[75]

Pseudomonasfluorescens, P. putida, P. alcaligenes,P. stutzeri, Comamonas acidovorans (formerly *P. acidovorans*), and*Comamonas*spp. have all been reported as pathogens.[74]

*Alcaligenes xylosoxidans*subspecies *xylosoxidans*can cause a wide array of clinical syndromes typical of other Gram-negative bacilli. Outbreaks have been linked to contaminated deionized water used for

hemodialysis, a contaminated diagnostic tracer, and the reuse of disposable pressure monitoring equipment.[17,76,77,78] *A. xylosoxidans* and *A. faecalis* have been reported as present in contaminated chlorhexidine, a phenolic germicide, and aqueous eosin.[55,77,79,80]

Chryseobacterium meningosepticum (formerly *Flavobacterium meningosepticum*) has been isolated from contaminated chlorhexidine and may grow in water with minimal nutritional requirements. Recent outbreaks have been related to a faulty pasteurizer tank and contaminated pressure transducers.[81,82]

Weeksella zoohelcum and *Weeksella virosa* were formerly considered part of the *Flavobacterium* genus. All these organisms have been reported to cause a spectrum of HAIs.[74]

Populations at Risk

These pathogens are generally considered low-virulence pathogens but are important throughout the world. They function as opportunists in hospitalized or institutionalized patients compromised by age, surgery, chemotherapy, or device use.

Laboratory Diagnosis and Procedures

In the bacteriology laboratory, simple media permit the growth of NFB, but selective media, such as MacConkey agar,[27,28,31] are generally chosen. Commercial systems are available for identification by genus and species.[83] Biochemical test patterns, colonial morphologic appearance, and antibiograms are useful strain markers for some Gram-negative bacilli, but antibiograms have less utility for organisms that are typically multiply resistant, such as *Acinetobacter, Stenotrophomonas*, and other NFB.[5] Although widely available and easy to perform, these methods frequently show only a modest capability to discriminate between strains that are often present in the environment or as normal flora.[83]

Historically, serologic typing and pyocin typing were the most widely used methods for studying the epidemiology of *P. aeruginosa*.[84] However, like phage typing and bacteriocin typing, serotyping has largely been replaced by molecular methods that are less variable and less cumbersome.[83]

DNA-based typing methods are somewhat limited by technical aspects of their performance, occasionally having complex banding patterns and a lack of a standard methodology used by all laboratories. However, they have gained acceptance as the best available methods for precise epidemiological typing of strains.[83,85,86] Typing by pulsed-field gel electrophoresis of genomic DNA can be reproducibly done. Initial studies using repetitive element sequence polymerase chain reaction demonstrated that these methods are useful and quite rapid.[87,88] These tests have gained popularity because they require less effort and expense. Analysis of plasmid or chromosomal DNA has been important in numerous epidemiological investigations.[83,84,85,89] Protein-based typing has been accomplished by a number of approaches, including immunoblot fingerprinting, polyacrylamide gel electrophoresis of cellular proteins, and multilocus enzyme electrophoresis, and have been used to aid epidemiological investigations.[83]

Pyrolysis mass spectrometry has been described as a rapid method for strain identification of *S. maltophilia*.[75] Whole-genome sequencing, a process determining the complete DNA sequence of a

microbe's genome, has been useful to resolve subtle differences between closely related isolates of multidrug-resistant *A. baumannii*in a military hospital setting.[90]

Susceptibility Patterns and Treatment Strategies

Antibiotic therapy is directed by in vitro susceptibility testing. Clinicians frequently must rely on combination therapy when treating these organisms empirically because antimicrobial resistance is common. Information regarding local patterns of antimicrobial resistance is vital. For *P. aeruginosa*bacteremia, combination therapy with an aminoglycoside and a beta-lactam with antipseudomonal activity is frequently continued because of a suggestion of improved survival with this approach.[11]*Acinetobacter*spp. and *S. maltophilia*in particular are prone to resistance to both aminoglycosides and cephalosporins.[48]In both of these cases, resistance to all commonly tested antimicrobial agents has been observed.[91]*S. maltophilia*is most reliably susceptible to trimethoprim-sulfamethoxazole and usually resistant to imipenem.[74]Controlled trials have supported the use of monotherapy in nongranulocytic patients with mild to moderate pseudomonal infections.[59]The primary concern about this approach has been the emergence of antibiotic resistance.

Prevention and Control Measures

Despite the rare naysayer who may criticize routine hand washing, the overwhelming opinion in the infection prevention community is that hand washing remains a primary means of preventing HAI.[4,92,93,94]It remains rare to find reports that raise the possibility of hand washing contributing to the spread of disease but commonplace to find epidemics linked to noncompliance with the practice of routine hand washing.[41]In a classic review of healthcare-associate bacteremia, Maki[95]cited more than 100 studies implicating hand carriage in the spread of Gram-negative organisms. Although Gram-negative organisms generally do not persist on intact skin for more than a few hours, it often is more difficult to prove transmission via the hands of healthcare personnel. Published literature supports the idea that greater availability of sinks for hand washing increases hand-washing behavior.[96]A variety of approaches, including strict segregation of patients with cystic fibrosis, based on carriage of this organism have been tried in order to reduce transmission of*B. cepacia*.[97]Both hospital outbreaks and social contacts outside the hospital have been implicated in transmission.[97,98]Contact Precautions also may play a role in the interruption of *A. baumannii*transmission.[99]

Areas of Controversy

A number of areas remain controversial in the prevention, diagnosis, and treatment of infections from NFB even for a single clinical condition such as ventilator-associated pneumonia.*Pseudomonas*spp. and *Acinetobacter* spp. are important causes of healthcare-associated pneumonia, and the role of selective decontamination of the digestive tract remains debated.[100]Similarly, the appropriate use of monotherapy versus combination therapy in the treatment of these infections remains contested.[101]Clinicians are also

examining new ways to shorten the duration of antimicrobial therapy for these important and common infections.[102] The appropriate role for invasive diagnostic testing for confirming ventilator-associated pneumonia remains controversial in part because of the lack of a gold standard for establishing the diagnosis.[103]

Financial and Cost-Benefit Issues

Most of the costs for preventing and managing these infections are not unique to the NFB. Environmental controls, hand hygiene programs, institutional surveillance, and the rapid response to evidence of epidemic or endemic infections result in benefit to patients in the form of reduced Gram-positive and Gram-negative infections.[104]

Conclusions

The prevention and control of HAIs from NFB remains an important challenge because of the frequent pathogenic role of these organisms in modern healthcare facilities worldwide. The continued frequent reports of outbreaks of these organisms highlight the multifactorial and multidisciplinary approaches needed for their control. Careful attention to safe device use, rapid diagnosis, and appropriate treatment will minimize their negative impact on patients.

Future Trends

There is still much to be learned regarding the prevention of infections secondary to NFB. No doubt, the taxonomy of these bacteria will continue to evolve, as will typing methods to rapidly identify epidemic strains coupled with information technology programs and computer systems to track and assess strain-specific information. Additional research is needed to help resolve a number of lingering questions. For example, most Category II recommendations from the *Guidelines for Environmental Infection Control in Health-Care Facilities* would benefit from the availability of additional relevant data, and many of these recommendations relate to the control of Gram-negative infections.[105]

International Perspective

Concerns and challenges regarding infection prevention and control programs globally have been recently reviewed.[106] Although the epidemiology of infections with NFB is less well defined in the third world, it is clear that limited resources challenge most hospitals in lesser developed countries. Fortunately, infection prevention appears to be gaining increased attention even where resources are restricted.

Abstract

The face of healthcare-associated fungal infection is changing. Candida*spp. continue to play a significant role, with high associated morbidity and mortality; however, non-*albicans Candida*spp. are increasing in incidence, as are opportunistic molds and other unusual fungal pathogens.*

The diagnosis of fungal pathogens has also undergone a major shift. New antigen and antibody tests, as well as rapid diagnostic polymerase chain reaction tests, are increasingly used.

Finally, the options for antifungal therapy are much broader. Newer azoles and echinocandins have proven as efficacious as traditional agents like amphotericin B, but with improved side effect profiles.

Key Concepts

- Fungi are increasingly being identified as healthcare-associated pathogens.
- Immunocompromised patients are at increased risk for fungal infections.
- *Candida*spp. are common endogenous flora.
- Exposure to antibiotics may predispose patients to *Candida*spp. infections.
- Most molds are ubiquitous in nature, making exposure unavoidable.
- Environmental controls may help reduce the risk of infection with certain fungi.
- Resistance to antifungal agents is well documented and now serves as a genuine clinical problem.

Background

This chapter reviews the epidemiology, clinical presentation, diagnosis, and treatment of fungal pathogens, with an emphasis on new developments. Endemic mycoses are briefly mentioned, but, as they do not generally cause healthcare-associated infections (HAIs), the remarks only highlight a few unusual aspects of these infections.

Basic Principles

- Patients at high risk for healthcare-associated fungal infections include patients with leukemia, patients with solid tumors and leukopenia, bone marrow transplant patients, injection drug users, patients who have undergone intra-abdominal or cardiothoracic surgery, burn patients, and premature or low-birth-weight infants.
- *Candida*spp. are the fourth most common cause of HAIs, but the epidemiology of *Candida*has been incompletely defined. Further prospective studies utilizing molecular typing techniques are needed to clarify the role of fomites and healthcare personnel (HCP) hands in the healthcare-associated transmission of fungi. Additional infection prevention strategies are needed, as mortality, morbidity, and cost from these infections remain high.
- A comprehensive guideline for the treatment of *Candida*infection has recently been published and should help to determine the best treatment for each patient circumstance.[1]
- Prevention of healthcare-associated *Candida*infections can be addressed by considering each risk factor for infection.
- *Aspergillus*spp. are ubiquitous molds found in decaying organic matter. The risk factors for development of invasive aspergillosis (IA) include steroids, prolonged neutropenia, and acquired immunodeficiency syndrome (AIDS). Multiple outbreaks have been reported in conjunction with intrahospital or surrounding construction.
- As in the treatment of *Candida*infection, newer azole agents and echinocandins offer new modalities of therapy to patients with IA. Similarly, comprehensive guidelines for the treatment for aspergillosis

have been published.[2]

- Strategies to decrease the incidence of IA fall into three broad categories: (1) decreasing the duration of neutropenia/corticosteroid use, (2) decreasing exposure of patients to conidia, and (3) prophylaxis in high-risk patients. Emphasis should be placed on prevention, as infection carries a high mortality.

Fungi Types

*CANDIDA*AND RELATED PATHOGENIC YEASTS

Identification

Fungi are eukaryotic organisms with cell walls containing chitin, cellulose, or both. Yeasts are unicellular organisms that reproduce by budding and typically, but not always, produce circular, mucoid colonies upon culture.

Clinically, the most frequently isolated yeasts are *Candida*, of which there are more than 80 species. *Candida*reproduces asexually by mitosis to produce blastoconidia. *Candida*appears Gram-positive. The cell walls also stain with Gomori methenamine silver stain and periodic-acid Schiff reagent.

In tissues, *Candida*may transform from blastoconidia (budding yeast cells) to pseudohyphae (elongated chains secondary to incomplete division), and finally into an extensive network of hyphae.[3]

*Candida*is a normal commensal of the human gastrointestinal and female genital tract. Phenotypically, it is identified by morphology of colonies on cornmeal agar plates, Gram stains, germ-tube formation (distinguishes *Candida albicans*from other *Candida*spp.), and carbohydrate assimilation (API systems).

Molecular biologic techniques that are helpful in epidemiologic investigations include restriction enzyme analysis (REA), electrophoretic karyotyping (EK), and DNA fingerprinting using polymerase chain reaction (PCR). Restriction enzyme analysis involves extracting DNA, cutting the DNA into large fragments with enzymes (infrequent cutters), and comparing the resulting DNA fragment sizes. Small differences in banding patterns may be missed as large fragments of DNA are compared.[4]EK involves the extraction and comparison of smaller fragments of DNA than can be achieved with REA. EK not only delineates species but can also delineate strain types that cannot be separated on the basis of phenotypic typing. DNA fingerprinting using PCR is rapid and simple and more sensitive in separating strain types than is EK.[5]

Epidemiology/Transmission

Fungi are increasingly identified as healthcare-associated pathogens. From 1980 to 1990, National Nosocomial Infections Surveillance Systems (NNIS, currently National Healthcare Safety Network) found that in participating hospitals, fungi comprised 7.9 percent of 344,610 healthcare-associated pathogens. Of these fungal infections, 79 percent were due to *Candida*spp.[6]Between 1991 and 2000, *Candida*was the fifth most common blood isolate and the fourth most common isolate from all sites in intensive care units (ICUs).[7]Most recently, among 2,039 hospitals reporting to the National Healthcare Safety Network (NHSN) between 2009 and 2010, *Candida*spp. accounted for about 9.5 percent of the 81,139 pathogens reported as etiological agents for 69,475 HAIs, becoming the fifth most common pathogen in HAIs.

Furthermore, *C. albicans*was the seventh most common cause of catheter-related bloodstream infections (BSIs) and the fourth most common cause of catheter-associated urinary tract infections (UTIs).[8]

Healthcare-associated candidemia accounts for 1.0 percent to 1.5 percent of hospital-acquired BSIs.[9]

Increases in healthcare-associated fungal infections have occurred at all hospitals, regardless of size or teaching affiliation. [10]In a study of 306 episodes of fungal BSIs in 34 participating centers, Pfaller et al. demonstrated that 80 percent were healthcare-associated. Fifty percent occurred in patients housed in ICUs.[9]In participating centers in the United States, 46 percent of the fungal BSIs were due to non-*albicans*species, most commonly *Candida glabrata.*[11]A recent multicentric study (PATH Alliance® registry), including 23 medical centers in the United States and two in Canada, confirmed these findings. This registry records invasive fungal infections (IFI) and reported 3,548 cases of infections by *Candida*spp, encompassing 53 percent of the IFI in the registry from 2004 to 2008. Most infections were caused by *C. albicans*(42.1 percent), followed by *C. glabrata*(26.7 percent), *C. parapsilosis*(15.9 percent), *C. tropicalis*(8.7 percent), and *C. krusei*(3.4 percent). *C. albicans*infections were more common among neonatal ICU (NICU) patients and patients in surgical units. *C. glabrata*was more common in older patients, patients with bone marrow transplants (BMTs) and solid organ transplants, and patients that had received previous antifungal therapy. *C. parapsilosis*infection has been associated with the presence of intravenous catheters and recent surgery and was commonly described in NICU patients. *C. tropicalis*was observed among BMT patients. *C. krusei*occurred most commonly among neutropenic, leukemic, or BMT patients.[12]

Patients at high risk for healthcare-associated fungal infections include patients with solid tumors, leukemia, and leukopenia; BMT patients; injection drug users; patients who have undergone intra-abdominal or cardiothoracic surgery; burn patients; and premature or low-birth-weight infants.[13]

General risk factors for *Candida*infection include receipt of broad-spectrum antibiotics, central venous catheterization, immunosuppression, neutropenia, urinary catheterization, prosthesis (e.g., vascular grafts), and total parenteral nutrition.[13]Risk factors specific to candidemia in postcardiac surgery patients include ongoing mechanical ventilation for 10 or more days, cardiopulmonary bypass for more than 120 minutes, and diabetes mellitus. APACHE (acute physiology and chronic health evaluation) II score of 30 or greater at onset of candidemia was an independent predictor of candidemia-related death in this population.[14]

In a prospective, multicentric observational study performed by the International Pediatric Fungal Network between 2007 and 2011, the authors enrolled 196 pediatric and 26 neonatal patients with candidemia. The most common predisposing factors in this cohort included hematological malignancies (19 percent), solid organ tumors (9 percent), gastrointestinal abnormalities (16 percent, the most common was short bowel), and surgery/trauma (15 percent—with the most common being abdominal surgery). Species other than *Candida albicans*accounted for the greatest number of cases of invasive candidemia (56 percent of pediatric cases, 52 percent of neonatal cases). However, among the individual *Candida*spp., *C. albicans*was the leading pathogen. Outcomes were best for *C. parapsilosis*and worst for *C. glabrata*.[15]

Compared with neonatal patients with coagulase-negative staphylococcal infections, neonates with candidemia had greater exposure to systemic steroids, antibiotics, and catecholamines, as well as a sevenfold higher mortality rate. Candidemic neonates were also more likely to have required mechanical

ventilation and less likely to be tolerant of enteral feeding.[16]Prolonged use of third-generation cephalosporins increased risk for candidemia.

A prospective cohort study of six geographically scattered NICUs from 1993 to 1995 resulted in 2,847 neonates enrolled. Of these, 1.2 percent developed candidemia, for a rate of 0.63 per 1,000 catheter days. Multivariate analysis, controlled for birth weight and abdominal surgery, revealed the following risk factors: gestational age under 32 weeks, 5-minute Apgar less than 5, shock, disseminated intravascular coagulation (DIC), prior use of intralipids, parenteral nutrition, presence of central venous catheter, H2 blockers, mechanical ventilation, or length of ICU stay greater than 7 days. Colonization of the gastrointestinal tract (GI) tract preceded candidemia in 43 percent of patients.[17]Postnatal steroids and necrotizing enterocolitis also increase fungal risk.[18]

*C. parapsilosis*is particularly common among neonates. Most neonates are colonized prior to developing infection, but colonization tends to occur later after birth, thus *C. parapsilosis*does not tend to cause early neonatal sepsis. Potential factors associated with *C. parapsilosis*in neonates include the use of cephalosporins, the presence of a central venous catheter, and use of total parenteral nutrition.[19]

A recent study based on population-based surveillance found that the incidence of candidemia among residents of Baltimore and Atlanta showed that the crude incidence of candidemia increased. The authors compared the rate of candidemia between 1992 and 1993 in Atlanta and 1998 and 2000 in Baltimore, with the rate of candidemia between 2008 and 2011 at each location. The rates of candidemia were highest among individuals over 65 years of age. However, the rate of candidemia was lower among infants less than 1 year of age, suggesting a change in the epidemiology of the disease.[20]

Patients with human immunodeficiency virus (HIV) are at risk to develop oropharyngeal candidiasis. This occurs when they have very low CD4 cell counts. The most common etiologic agent is *C. albicans*, but other species like *C. glabrata*and *C. dubliniensis*have been implicated. Patients receiving antiretroviral therapy have a lower risk of developing oropharyngeal candidiasis, whereas those with a history of esophageal candidiasis or wearing dentures are at risk of colonization with fluconazole-resistant organisms. Most patients respond to therapy with fluconazole, but the dose may need to be increased when clinical response is not achieved.[21]

In solid organ transplants, the incidence of fungal infections has increased, with recent prospective data showing an incidence of 3.1 percent for any invasive fungal infection.[22]*Candida*spp. were responsible for the majority of disease, with mortality seen in 66 percent of those with invasive candidiasis.

Previously, it was felt that most episodes of *Candida*infection have resulted from the patient's own endogenous flora.[23]Recently, however, patient-to-patient transmission has been implicated. The precise role fomites play in the epidemiology of hospital-associated *Candida*infection is still being investigated.

HCP hands have been shown to harbor *Candida*spp., and molecular studies have suggested that transmission through the hands of HCP may contribute to outbreaks.[24]In a prospective study of 25 patients with third-degree burns and receipt of 10 to 14 days of broad-spectrum antibiotics, 75 percent of the patients diagnosed with invasive yeast by skin biopsy were previously colonized with the same organisms. In addition, multiple surfaces in the burn unit were heavily contaminated with yeast. However, no biotyping was done to show whether strains were related.[25]

Yeasts have been detected on 80 percent of HCP hands, and *Candida*spp. have been recovered from 63 percent of nurses studied. The best method for recovery of yeasts from HCP hands appears to be a bag wash in brain/heart infusion broth supplemented with gentamicin and vancomycin.[26]During a recent outbreak of neonatal infection with *C. parapsilosis*, the hands of one of the NICU physicians was found to have the same molecular pattern (using random polymorphism DNA analysis) as two of the three patients involved, and a strain on the hands of a nurse was found to be consistent with the third case.[27]

In an attempt to document healthcare-associated transmission, Taylor et al. performed DNA fingerprinting of 91 *C. albicans*isolates from 32 patients in an ICU. The isolates from individual patients were distinct, revealing no cross-transmission.[28]

An outbreak of *C. parapsilosis*has been traced to a contaminated vacuum transfer pump used to prepare parenteral nutrition solutions.[29]Similarly, an outbreak caused by a single strain of *C. glabrata*was responsible for nine infections in a pediatric population in Turkey. The source was thought to be bottles used for milk feeding that had been improperly handled.[30]

*C. parapsilosis*has also been shown to be healthcare-acquired in BMT patients, with REA analysis showing one strain common to four patients, three staff members, and two environmental surfaces.[31]

Congenital or perinatal infection with *C. glabrata*has been described in neonates.[32]Patients with newly acquired *C. glabrata*colonization or infection had longer durations of hospitalization and more frequent prior antimicrobial use than patients from whom *Candida*species were not recovered.[32]Also, patients generally carried the same strain type of *C. glabrata*longitudinally. Hands of HCP did not appear to be a factor in transmission. In a BMT population, 71 percent of patients that cultured positive for *C. glabrata*also carried other *Candida*species.[33]

In a retrospective case control study of patients with and without candidemia from July 1, 1997, to June 30, 2001, the crude mortality for candidemia was 61 percent. Attributable mortality was 49 percent, highlighting the seriousness of these infections. The cost of candidemia is estimated to increase hospital costs by $6,000 to $29,000 per episode and the length of hospital stay by 3 to 13 days.[34,35]Similar results were reported in a group of patients by Dodds Ashley et al., including data from 119 patients with candidiasis. The attributable costs, adjusted for sex, age, race-ethnicity, and number of comorbid illness was $38,734 in 2004 dollars.[36]

The epidemiology of *Candida*is in its infancy. Further prospective studies utilizing molecular typing techniques are needed to clarify the role of fomites and HCP hands in the healthcare-associated transmission of fungi. Additional prevention strategies are needed, because mortality, morbidity, and cost from these infections remain high.

Diagnosis

*Candida*can be isolated from mouth washings of 50 percent of healthy persons and in the stool of 90 to 100 percent of halthy adults. For this reason, isolation of *Candida*spp. from mucosal surfaces and nonsterile body sites (mouth, rectum, vagina, skin) is not diagnostic of disease.

Mucosal (vaginal or mucocutaneous) candidiasis is typically diagnosed by appearance of the mucosal plaques, symptoms, and 10 percent potassium hydroxide preparation of fresh scrapings to look for

budding yeast cells and pseudohyphae, with positive follow-up culture.

The diagnosis of UTI can be difficult, especially in patients with indwelling bladder catheters. Typically the urine will contain more than 5 white blood cells (WBCs) per high-power field, as well as being positive for leukocyte esterase and/or nitrites, with culture growing greater than or equal to 10^5 colony forming units (cfu)/mL of *Candida*. Even 10^5 cfu/mL titers of candiduria may fail to differentiate colonization from infection in the catheterized patient. Upper tract disease should be suspected if candidal casts (hyphal casts) are present in a fresh urine sample,[37] or fungal balls are seen in the kidneys on ultrasonography.

Fungal organisms isolated from a normally sterile body site concurrent with signs and symptoms of infection are diagnostic of deep tissue or disseminated infection. Tissue samples show the presence of yeast cells plus hyphal forms on appropriate staining.

Disseminated candidiasis can be diagnosed by positive blood cultures, but unfortunately current blood culture systems may miss up to 50 percent of invasive candidiasis.[38] Accordingly, a negative blood culture does not exclude invasive candidiasis.

1,3-beta-D-glucan detection is emerging as a useful method of diagnosis of invasive candidiasis. Results can be obtained within 72 to 96 hours, as the test is usually a "send-out" to a specialized laboratory. Sensitivity ranges from 70 to 80 percent and increases if multiple sequential surveillance specimens are available. Also important is the negative predictive value (NPV) of two negative beta-D-glucan tests in ruling out invasive candidiasis, especially in a high-risk febrile patient with NPV greater than 98 percent.[39]

Real-time PCR has also been examined and compared to conventional blood cultures and 1,3-B-D-glucan (BDG) testing in the diagnosis of candidiasis. PCR using plasma or sera was more sensitive than BDG testing for diagnosing invasive candidiasis with similar specificity, and PCR was more sensitive for deep-seated candidiasis. PCR and BDG testing were both more sensitive than blood cultures for deep-seated candidiasis.[40]

Following isolation of *Candida* spp. in blood fluid or tissue samples, it is essential to identify the causative organism to the species level allowing for more rapid determination of antifungal drug susceptibility. All laboratories should ensure rapid species identification even for urinary and mucosal isolates. For blood isolates, rapid *Candida* identification within 3 to 4 hours is possible using multiple different methodologies that are currently available (PNA FISH, MALDI-TOF, or chromogenic agar—though the later requires identification of colony phenotype).[41,42]

It is hoped that in the near future, these newer diagnostic modalities will allow early detection and therefore earlier treatment of fungal infections.

Clinical Manifestations

Clinical manifestations of *Candida* infection vary with the organ system involved. Oral and mucosal candidiasis often presents with alteration of taste and dryness of the mouth as well as tongue soreness and pain. Esophageal candidiasis presents as dysphagia with odynophagia.

Vaginal candidiasis commonly presents with "cheesy" white vaginal discharge and vulvovaginal burning or itching, as well as burning on urination because of periurethral irritation.

Urinary tract signs and symptoms depend on whether cystitis or upper tract disease is present. Cystitis presents with dysuria, frequency, urgency, and nocturia, as well as suprapubic pain. Fortunately, an ascending infection is rare. Upper tract disease presents with fever, flank pain/tenderness, and rarely secondary candidemia. It is more common in patients with diabetes, especially in association with obstruction, and is further complicated by papillary necrosis or fungal balls in the urinary tract as demonstrated by ultrasound.[37]

Disseminated candidiasis should be suspected in high-risk patients with unexplained fever (especially in the immunocompromised host on broad-spectrum antibiotics), unexplained central nervous system signs and symptoms, or clinical deterioration in a compromised host.

Complications of candidemia/disseminated candidiasis include endophthalmitis, endocarditis, or purulent pericarditis; meningitis; suppurative thrombophlebitis; and vertebral osteomyelitis. Hepatosplenic candidiasis is typically seen in severely immunosuppressed patients and presents as fever, hepatosplenomegaly, and elevated alkaline phosphatase with a typical appearance on computed tomography (CT) scan of multiple small hypodense lesions in the liver and spleen.[1]

Pathogenesis

Colonization of the oropharynx and GI tract has been shown to increase with hospitalization, with more *C. albicans* species in the mouth, and more non-*albicans* species in the rectum and urinary tract.[43]

Antibiotics predispose to *Candida* infection by reducing the normal bacterial flora and allowing *Candida* to proliferate. The most important defenses against *Candida* are intact integument and mucosal barriers. *Candida* can enter the vascular system via peripheral or central catheters or injection drug use. Urinary catheters provide an irritative focus and mucosal ulcerations allowing the fungi to traverse bladder mucosa, in the same way that chemotherapeutic agents, irradiation, and GI surgery disrupt oral and gut mucosa, allowing *Candida* a portal of entry into the vascular system.

Neutrophils are the main line of defense against fungi, as they ingest and kill blastoconidia. However, hyphae in tissues are more resistant to phagocytosis.[44] *Candida* are killed in phagosomes by myeloperoxidase, hydrogen peroxide, superoxide anion, and chymotrypsin-like cationic proteins.[45]

Lymphocytes and cell-mediated immunity play a role in the host defense against superficial candidiasis, as evidenced by the fact that AIDS patients are more prone to develop mucocutaneous candidiasis. Once candidemia occurs, the potential exists for microabscess formation in a variety of tissues.[46]

Treatment

Mucocutaneous candidiasis is best treated with oral or topical azoles (the later reserved solely for vulvovaginal candidiasis), unless the infection becomes recurrent or refractory.

Lower UTIs, if asymptomatic (especially in patients with indwelling urinary catheters), do not require treatment. Symptomatic UTIs, especially upper tract disease, require systemic antifungals.

The mortality of candidemia is high, typically 50 to 75 percent.[13,22,47] Mortality is virtually 100 percent if the patient remains persistently neutropenic.[9] Delay in diagnosis invariably translates into delay in initiation of appropriate antifungal therapy and higher mortality.[48] The gold standard for therapy of fungemia or disseminated candidemia previously was intravenous amphotericin B (AmB); however,

recent studies have shown that parenteral azoles (fluconazole, voriconazole) or the echinocandin drug class are as effective and less toxic with echinocandins use associated with lower mortality in a recent meta-analysis.[49]

The characteristics of an ideal antifungal would be broad spectrum of activity, fungicidal activity, lack of development of resistance during therapy, availability of both oral and intravenous (IV) forms, good penetration into body fluids, and lack of toxicity.[50]To date, no agent is available that meets all these criteria, but some of the newer azole agents and echinocandins come close and have replaced AmB as first-line therapy for systemic candidiasis.[1]

A comprehensive guideline for the treatment of *Candida*infection has recently been published and should help to determine the best treatment for each patient's circumstances.[1]

Development and Impact of Resistance to Antimicrobial Agents

The recent standardization of methods of performing minimum inhibitory concentration (MICs) in fungi has facilitated the detection of resistant strains.[51]Correlation between in vitro MIC data and in vivo response to therapy remains incomplete; however, use of in vitro susceptibility is increasingly available and facilitates treatment.

In general, *C. lusitaniae*is less susceptible to AmB and can develop resistance to AmB while on therapy.[52]*C. glabrata*isolates are also intrinsically less susceptible to AmB, as well as all available azole agents, but are highly susceptible to the echinocandin class of antifungals.[53]

Primary resistance to fluconazole is present in *C. krusei*, which fortunately remains an infrequent cause of invasive disease.[54]Studies by Pfaller et al. suggest that drug-resistant isolates of *Candida*spp. may emerge from among endemic strains.[55]

AmB resistance is felt to be secondary to changes in ergosterol content of fungal cell membranes. One study has shown BSIs in immunocompromised patients caused by yeast isolates with MICs greater than 0.8 µg/mL to be 100 percent fatal, versus 47 percent mortality if MICs are 0.8 µg/mL or less.[56]Of considerable concern were the numerous reports of *C. albicans*resistance to fluconazole in patients with advanced AIDS, resulting in azole-resistant mucosal candidiasis; however, with the availability of active antiretroviral therapy (ART), refractory oral and esophageal candidiasis due to azole-resistant *Candida*spp. has decreased considerably.

In a global susceptibility study from 1997 to 2007, yeast isolates from 41 countries were collected.[57] From the beginning of the study period to December 2007, the proportion of isolates that were *C. albicans*decreased, whereas *C. glabrata*, *C. tropicalis,*and *C. parapsilosis*isolates increased in frequency. Although resistance to fluconazole varied by country, the overall rate of susceptibility to fluconazole remained stable and infrequent. Voriconazole had a 10- to 100-fold greater in vitro activity against most yeast species than fluconazole, but this has not turned out to be an advantage in treatment of candidiasis syndromes with rare exceptions.

*C. albicans*can be separated into five clades or groups: I, II, III, SA, and E. The predominant clade varies geographically. Flucytosine resistance is found almost exclusively in clade I organisms.[58]

*C. glabrata*vaginitis refractory to azoles has been successfully treated with topical boric acid or topical flucytosine cream.[59]

Accordingly, *C. glabrata*emerged as the Achilles heel of the entire azole drug class, including voriconazole and posaconazole. Fortunately, echinocandin agents are broad-spectrum fungicidal agents against *Candida*, and in vitro and clinical resistance is uncommon though increasingly reported.[60]

Although *C. parapsilosis*isolates have higher MICs to echinocandins, this has not translated into clinical resistance, yet caution is still recommended during treatment of *C. parapsilosis*with this class.[1]

Prevention and Risk Reduction

Prevention of healthcare-associated *Candida*infections can be addressed by considering each risk factor for infection.

Judicious use of antibiotics will decrease *Candida*overgrowth in oral, vaginal, and gut mucosa. Central venous catheters should also be used only when indicated, and aseptic technique should be followed when the catheter is inserted and accessed.

Oral nutritional solutions should be used whenever possible. When parenteral nutrition becomes necessary, total parenteral nutrition solutions should be mixed in the pharmacy in laminar flow hoods using aseptic technique; bags should not be respiked; and solutions containing lipids should have a hang time of no more than 12 hours.[29]

The prophylactic or empirical use of oral fluconazole is widely practiced and has been shown to decrease the incidence of fungal infections in neutropenic patients, but unfortunately no effect on mortality was seen.[61]A similar trial in the ICU showed no improvement in the composite outcome when prophylactic fluconazole was prescribed compared to placebo.[62]Additionally, as more institutions used prophylactic azoles, problems with azole-resistant fungi such as *C. glabrata* increased.[63]Patients receiving chemotherapy, those at risk for neutropenia, those in ICUs with high rates of candidemia, and those with high risk solid or BMT should receive antifungal prophylaxis, usually with an azole.[64]

Antifungal prophylaxis in neonates has been shown to decrease rates of candidiasis among neonates, and in units where rates of candidiasis are elevated, fluconazole prophylaxis is recommended particularly among neonates born before 27 weeks' gestation or those weighing less than 1,000 grams.[65]

Among patients with HIV and recurrent mucocutanous candidiasis, fluconazole has been shown to decrease the number of recurrences.[1]

ASPERGILLUS

Identification

*Aspergillus*spp. are ubiquitous molds found in decaying organic matter. Conidia (spores) are inhaled, followed by germination and appearance of 2- to 5-µm wide hyphae that are frequently septate and branch at 45-degree angles. Histologic appearance in tissue can be confused with *Fusarium, Scedosporium*, and other hyaline molds; therefore, culture confirmation is necessary.

Epidemiology/Transmission

The route of acquisition of *Aspergillus*is typically via inhalation of conidia (spores), which are ubiquitous in nature and within the hospital environment (potted plants, flowers etc).[66]

The risk factors for development of IA include leukemia, lymphoma, receiving high-dose or prolonged corticosteroids, prolonged neutropenia, solid organ transplant, and AIDS.[67]Patients at risk include those with aspergillosis, which was the second most common invasive fungal infection on the Path Alliance registry. It encompassed 1,001 isolates, of 7,525 isolates included. The most common species causing disease were *A. fumigatus*(543; 54 percent of total *Aspergillus*infections), *A. flavus*(74 cases; 7.4 percent), *A. niger*(65 cases; 6.5 percent), *A. terreus* (32 cases; 3.2 percent), and other species (34; 3.4 percent).[68]

In a subset of the Path Alliance Registry, among patients with hematopoietic stem cell transplant, IA was the most common cause of IFI (59 percent), followed by invasive candidiasis and other mold infections. Invasive fungal infection in this population occurs more frequently among allogeneic BMTs (68.8 percent) than among autologous BMTs (31.2 percent). *A. fumigatus*was the most common isolate. Among *Candida*IFI, most cases included non-*albicansCandida*, including *C. glabrata*. Researchers observed a trend toward fewer *Aspergillus* infections and more Mucorales (zygomycoses) infections, perhaps due to the common utilization of voriconazole for IFI prophylaxis.[69]

Another study based on autopsies over a 20-year period at a reference cancer center (1989–2008) observed a lower rate of IFI as patients age, with only Mucorales showing a significant increase over time. Among *Aspergillus*spp. isolated in this study, *A. fumigatus* was the most common. This study was limited by the fact that many *Aspergillus*spp. infections were identified based on histopathology, but cultures were frequently negative.[70]

One pseudo-epidemic occurred in a pediatric BMT unit due to faulty storage of culture plates. Stored plates on a shelf in a laboratory responsible for culturing clinical samples with resultant increased number of airborne conidia was the source of the pseudo-outbreak.[71]

Multiple outbreaks have been reported in conjunction with intrahospital or surrounding construction.[68]An outbreak in a renal transplant unit involving 10 patients was associated with window air conditioners heavily colonized with *A. flavus*and *A. fumigatus*at a time when there was construction adjacent to the hospital.[72]

The importance of airborne transmission was evidenced by an outbreak of *Aspergillus*infection among heart transplant patients. During this outbreak, there were seven cases of IA among heart transplant patients (compared to no cases in the pre-intervention period). The cases included six cases of invasive pulmonary aspergillosis (one with mediastinitis), and one case of mediastinitis. All cases except one had *A. fumigatus*isolated. The hospital performed routine air samplings with fungal cultures at least monthly. They found that the air in the operating rooms did not contain detectable conidial counts; however, the spore levels in the major heart surgery ICU were between 20 and 400 cfu. Furthermore, the strains isolated from the environment were genotypically similar to those of the patients in three of the six isolates that underwent genotyping testing. Despite the strong correlation with the presence of *Aspergillus*conidia on the air and this outbreak, there is not a clear threshold in the conidial count beyond which intervention is recommended, although greater than 16.7 cfu/mm^{3}has been proposed.[73]

Environmental sources of *Aspergillus* outbreaks in hospitals have been associated with open windows,[74] contamination of particle board frames surrounding air filters,[75] backflow of contaminated air from exhaust ducts (with contamination of filters),[76] gaps in filters and support frames permitting entry of unfiltered outside air,[77] and contamination of humidified cell culture incubators in a laboratory culturing lymphokine-activated killer cells for reinfusion into patients.[78]

An outbreak of 10 cases in 26 BMT patients in New York was associated with hospital construction in a BMT unit with 10 percent efficiency of filtration and less than five air exchanges per hour. This was the first report of a higher incidence of aspergillosis associated with chronic myelogenous leukemia and aplastic anemia.[79]

A prospective study of 23 U.S. transplant centers found that *Aspergillus* spp. were responsible for 19 percent of all IFIs in solid organ transplant recipients.[22] In hematopoietic stem cell transplant recipients, however, aspergillosis was the most common IFI (43 percent), exceeding even that of invasive candidiasis (28 percent).[47] Aspergillosis generally occurs within the first 120 days after stem cell transplant.

In one university hospital, the proportion of invasive *Aspergillus* infections caused by *A. terreus* has been increasing relative to other *Aspergillus* spp. Molecular typing showed strain diversity among isolates, so no common source is suspected. The etiology for the increase is unknown.[80]

Many difficulties arise in determining whether a case of IA is healthcare- or community-associated. The first of these is that many patients are discharged and readmitted or allowed out on passes. Second, surveillance culture results alone do not accurately reflect the true number of IA cases, as they are often not diagnosed antemortem; therefore, autopsy records must also be reviewed. Even with the inclusion of autopsy cases, deceased patients with IA who do not undergo autopsy will be missed. Third, reactivation of endogenous organisms may produce infection, as evidenced by the fact that 50 percent of patients with acute myelogenous leukemia developed IA, whereas those suffering neutropenia developed a second episode of IA during subsequent chemotherapy-induced granulocytopenia. Fourth, *Aspergillus* strains in the hospital environment may be genetically diverse.[81]

Diagnosis

As discussed, *Aspergillus* in histologic sections can be confused with other pathogenic molds. For this reason, confirmatory culture data are essential. The combination of histology and positive culture is the gold standard for diagnosis.[82]

The poor candidacy of many patients with suspected IA for surgical or other diagnostic procedures has increased interest in noninvasive testing. The galactomannan enzyme immunoassay (EIA) has been proven reliable in patients with hematologic malignancy; however, the reported sensitivity varies greatly (44 to 90 percent).[83,84] False-positive results have been reported in patients receiving semisynthetic penicillins (piperacillin-tazobactam and amoxicillin-clavulanate) and in those infected with the dimorphic fungi *Histoplasma capsulatum* or *Blastomyces dermatididis* due to the presence of galactomannan in these species as well.[85] Serial EIA testing of high-risk patients is recommended, though the testing frequency remains unclear and murine models have demonstrated the utility of daily screening given the

rapid tissue destruction of invasive pulmonary aspergillosis (IPA) in neutropenic hosts.[86] Serum galactomannan determination also provides prognostic information with declining values associated with improvements in patient outcomes.[87]

Serum BDG (a component of the fungal cell wall) determination also may be helpful, though this marker is not specific for *Aspergillus* and its presence may indicate a number of invasive fungal infections.[88] The negative predictive value of BDG has generated interest in its use as a screening test in high-risk patients.[89]

PCR-based methods have also been evaluated and appear promising, but testing is not yet cleared by the U.S. Food and Drug Administration for the diagnosis of *Aspergillus.*[90] The use of multiple concurrent modalities has not been prospectively evaluated but may be a significant advance in noninvasive diagnostic testing for *Aspergillus* spp.[91] Caution must be exercised in the interpretation of radiographic imaging, as chest radiographs may be unremarkable in patients with pulmonary symptoms, whereas CT scans or magnetic resonance imaging (MRI) show extensive pulmonary involvement. CT scan of the chest can be diagnostic if the halo sign (a zone of intermediate attenuation surrounding a higher-attenuation mass and separating it from the surrounding parenchyma) is seen.[92]

MRI has yet to be studied extensively in IPA. The diagnosis of IPA with use of MRI may be rather problematic, because MRI findings are not as characteristic as the CT findings during the early course of IPA.[93]

Clinical Manifestations

Sinus involvement by *Aspergillus* can present as allergic fungal sinusitis with rhinorrhea and nasal obstruction or invasive sinusitis with vascular invasion.[94]

Several forms of pulmonary *Aspergillus* disease are described. Allergic bronchopulmonary aspergillosis is seen in patients with preexisting asthma in association with eosinophilia, elevated immunoglobulin E (IgE), and fleeting pulmonary infiltrates. Patients often cough up hyphal plugs, and the treatment of choice is itraconazole in an attempt to avoid corticosteroids.[95]

Aspergillomas are fungal balls that may form their own cavity or develop in a preexisting lung cavity (e.g., bullous emphysema or sarcoidosis). Patients often present with hemoptysis, and the treatment of choice is surgical because of poor penetration of antifungals into cysts or cavities. Patients with chronic granulomatous disease are more prone to IPA with pneumonia and insidious onset of fever.[96]

IPA is associated with immunosuppression, steroids, and neutropenia. Patients develop fever, dense pulmonary infiltrates, hemoptysis, and/or pleuritic chest pain; however, the lack of an immunologic response due to underlying-host defects mandates a high level of clinical suspicion for infection. The disease is rapidly fatal if untreated. As neutropenia resolves, lesions tend to cavitate.[97] IPA mortality ranges from 65 to 100 percent but is invariably fatal if neutropenia persists.[98,99]

Disseminated disease involves multiple organ systems, but concurrent lung involvement is almost always observed.

A major patient group recently recognized as being high risk for IPA includes those with chronic obstructive pulmonary diseases (COPD) or those with a prolonged course in the ICU.[100]

Pathogenesis

*Aspergillus*conidia are ubiquitous, and thus environmental exposure is largely unavoidable. In allergic bronchopulmonary aspergillosis, the fungus does not invade lung tissue but remains in paranasal sinuses and ectatic bronchi, eliciting an IgE antibody-dependent reaction with prominent sputum eosinophils.

In immunosuppressed patients, germination occurs, followed by vascular invasion and tissue infarction, necrosis, and hemorrhage. In autopsy studies of patients with IA, the majority ultimately succumb to pulmonary hemorrhage.[101]

Neutrophils and macrophages are of paramount importance in host defenses against aspergillosis. Granulocytes damage hyphae by phagocytosis and oxidative killing.[102]

Cell-mediated immunity probably plays a role, albeit a lesser one, as evidenced by the fact that AIDS patients are more prone to IA owing to leukocyte and macrophage dysfunction secondary to abnormalities of T-cell function and increasing use of corticosteroids.[103]

Also, the use of OKT3, which decreases T-cell immunity, predisposes patients who undergo liver transplantation to IA independent of steroid use.[104]

Treatment

The gold standard of therapy previously was high-dose (1.0 to 1.5 mg/kg/d) intravenous AmB deoxycholate; however, a major factor contributing to the lack of success with AmB deoxycholate was dose-limiting toxicity, especially nephrotoxicity.

Voriconazole, available both orally and intravenously, is now considered the drug of first choice for IA. A prospective randomized study showed superiority when compared with AmB deoxycholate and significantly reduced mortality at 12 weeks.[105]Duration of therapy depends on the immune status of the patient involved and often continues for several weeks or months.[67]Blood levels of voriconazole must be obtained frequently to both ensure that adequate levels have been achieved (greater than 2 µg/mL) and attempt to avoid toxicity (which occurs more frequently with levels greater than 5 µg/mL).[106]There are multiple potential drug interactions with concomitant-administered drugs, and potentially interactions should be reviewed before prescribing.

Posaconazole is another broad-spectrum triazole related to itraconazole. It has similar in vitro activity as voriconazole and enjoys a safer toxicity profile; however, posaconazole is not available parenterally. Although used as treatment for IA in some cases, posaconazole is typically used for antifungal prophylaxis in patients with acute myelogenous leukemia or with graft-versus-host disease.[107,108]

Itraconazole, an orally available azole considered second-line therapy for IA.[109]has good in vitro activity against *Aspergillus*. Side effects include edema, nausea and vomiting, rash, hypokalemia, and elevated liver function tests. Side effects are more commonly seen with doses exceeding 400 mg/day. Failure rates with itraconazole are in the 30 percent range. Itraconazole, now only available as an oral

preparation, is not a first-line therapy but occasionally is used as maintenance after initial induction therapy.

Experience with echinocandins for aspergillosis is limited to retrospective series; however, a combination therapy trial evaluating voriconazole plus anidulafungin versus voriconazole alone has recently been completed, though the results have not yet been published.

Lipid formulations of AmB (liposomal AmB and lipid complex AmB) at higher doses of 5 mg/kg/d have largely replaced AmB deoxycholate, demonstrating considerably less but not absent nephrotoxicity.[67]

Prevention and Risk Reduction

Strategies to decrease the incidence of IA fall into three broad categories: (1) decreasing the duration of neutropenia/corticosteroid use, (2) decreasing exposure of patients to conidia, and (3) prophylaxis in high-risk patients. Emphasis should be placed on prevention, because infection carries a high mortality.

Strategies for prevention of aspergillosis in healthcare settings include education of the staff to suspect the disease in patients with predisposing conditions. Susceptible patients should be protected against exposure. Exposures include conidia, which may be found in the air and water. Management of the air delivered to patients with BMT is particularly important. BMT patients should be placed in rooms with at least 12 air exchanges per hour, with high-efficiency particulate air (HEPA) filtration, ideally with positive pressure when compared to the corridor, and well-sealed windows. Doors should remain closed whenever possible. In centers that provide BMT, construction should be thoroughly monitored, and an infection control risk assessment is strongly recommended for all construction projects. Construction projects require solid barriers and negative pressure ventilation. It is important to note that even projects outside the building may increase the air contamination if located close to the air intake, so the air intake may need to be sealed. Planning for construction should be performed by a multidisciplinary team, including infection control. BMT patients should avoid construction sites, and supplies should not be transferred through construction sites to avoid contamination. Spore control activities should be enhanced, with particular emphasis on proper ventilation (usually negative and ventilating outside) on indoor construction sites. Carpeting should be avoided in BMT areas, and dust-generating activities should be precluded. Water leaks should be promptly repaired to avoid mold growth.[110]

Hand hygiene, avoidance of crowded areas of the hospital, proper cleaning, and disinfection of equipment are also important. Flowers and potted plants should not be allowed in areas where immunosuppressed patients are admitted, as they may harbor *Aspergillus*spp. and other fungi.[110,111]

Decreased risk of IA has also been shown in liver transplant patients with the use of tacrolimus for posttransplant immunosuppression, probably by decreasing the need for steroids.[112]

Decreased incidence of pulmonary IA has also been shown with nebulized AmB as well as low-dose IV AmB.[113]Randomized control studies have shown efficacy in preventing invasive fungal infection,

especially aspergillosis, with daily oral posaconazole, which was superior to fluconazole and itraconazole in both patients with prolonged neutropenia or graft-versus-host disease receiving steroid therapy.[107,108]

Patients who suffered IA while undergoing chemotherapy should be given prophylaxis during subsequent treatments until resolution of neutropenia.[67]

Endemic Mycoses

Because endemic mycoses are generally not passed person to person in the healthcare setting, a full discussion of *blastomycosis*, *histoplasmosis*, *cryptococcosis*, and *coccidioidomycosis*is beyond the scope of this chapter. However, several interesting cases are presented in brief.

Cases of disseminated, fatal *coccidioidomycosis*have occurred in organ transplant recipients from unrecognized donor infection at the time of transplant; in fact, isogenicity has been proven by whole-genome sequencing.[114]Transplant patients have also been reported to develop invasive cryptococcosis from asymptomatic organ donors.[115]These cases typically present very early after transplantation, with disease that appears to occur preferentially in liver transplant recipients and involves unusual sites, such as the transplanted organ or the surgical site. These patients may have unrecognized pretransplant or donor-derived cryptococcosis.

Past reports have also observed outbreaks of histoplasmosis in an inpatient facility. Fifty-seven pediatric patients, the majority undergoing treatment for acute leukemia, were diagnosed with histoplasmosis. In this population, histopathologic examination of localized lung tissue and *Histoplasma*urine antigen testing were helpful in making the diagnosis. Patients were treated with AmB followed by a prolonged course of azole drugs with a 100 percent success rate.[116]

These cases illustrate the varied presentation of endemic mycosis in today's hospitalized patients.

MISCELLANEOUS FUNGI ASSOCIATED WITH HEALTHCARE-ASSOCIATED OUTBREAKS

For diseases that occur sporadically, like invasive fungal infections caused by an unusual fungal agent, when two or more cases of an infection are detected, an outbreak should be suspected. A recent review of the literature was able to characterize 36 such outbreaks reported between 1990 and 2011 (excluding *Candida*and *Aspergillus*). Duration of the outbreaks was variable, and among the 18 outbreaks where the source was identified, 16 were due to contaminated devices or solutions, and two occurred through transmission from a nurse's hands. Most outbreaks occurred in ICUs, and the time between cases was a median of 30 days (this emphasizes the importance of maintaining a high level of suspicion). In surgical patients, infections are most likely due to inoculation or contact with contaminated substances; in immunocompromised patients, infection occurs through inhalation, injection, or ingestion of contaminated substances. Mortality is elevated and duration of the epidemic tends to be shorter when the source of the infection is detected.[117]

Invasive fungal infections by non-*candida*, non *Aspergillus*yeast and molds include Mucormycetes (in particular *Lichtheimia*, *Rhizomucor,*and *Rhizopus*), endemic mycosis and other molds (such as *Acremonium, Alternaria, Bipolaris, Fusarium*, *Scedosporum*), and some yeast (*Cryptococcus*, *Malassezia, Pneumocystis, Rhodotorula, Saccharomyces, Trichosporon*), among others.[68]

Exserohilum rostratum

*E. rostratum*was implicated in a large national outbreak of fungal meningitis occurring among patients receiving methylprednisolone spinal injections. The median time from injection to disease was variable (range 12 to 121 days). Fever, headache, worsening back pain, cauda equina syndrome, and posterior circulation stroke were reported among the first cohort of cases reported from a Tennessee clinic. Most patients had granulocytic pleocytosis on the cerebrospinal fluid, with high total protein and low glucose. Risk for infection was associated with the use of contaminated lots of methylprednisolone, female gender, translaminar epidural glucocorticoid injection, and multiple procedures.[118]The U.S. Centers for

Disease Control and Prevention (CDC) reports that there were 741 cases reported in 20 states and that only 32 percent of the cases had laboratory-confirmed disease. The source of the infection was the New England Compounding Center in Framingham, Massachusetts, which compounded three lots of contaminated methylprednisolone for injections.[119]

Microsporum canis(Ringworm)

*M. canis*causes infections of keratinized areas of the body (skin, hair, nails) and fluoresces yellow-green under a Wood's lamp. An outbreak of six cases in a preterm level II nursery were traced to an asymptomatic nurse. All six patients had breaks in skin integrity at the site of infection.[114]An additional outbreak was reported from another NICU. The source was a nurse whose cat was sick with *M. canis;* the outbreak involved six patients, each of whom developed cutaneous involvement. The outbreak was controlled with contact isolation of affected cases, removal of the nurse from service, and treatment of her and her cat. [120]Several outbreaks in schools have been reported. In a recent report, six cats, four dogs, and four veterinarian students developed cutaneous involvement after contact with stray cats. The possibility of cutaneous infection transmission may be an important consideration when allowing animals in healthcare settings.[121]

*Scedosporium*spp.

*Scedosporium*is a fungus that most commonly causes mycetoma. Inhaled spores can lead to disseminated disease, which is rapidly fatal in immunocompromised patients. A case is described of healthcare-associated acquisition in a post liver transplant patient. The organism is a ubiquitous soil fungus that is resistant to AmB but sensitive to itraconazole, posaconazole, and voriconazole.[83]

Healthcare-associated clusters of disease secondary to *Scedosporium* spp. have been reported. The case involved six patients with acute nonlymphocytic leukemia who developed disease after inhalation of the organism. Environmental air sample isolates were similar to those from affected patients.[122]

Saksenaea vasiformis

*S. vasiformis*is an agent in the order Mucorales that is isolated from soil. A case is described of a motorcycle accident patient who was on corticosteroids for closed head trauma who developed extensive necrosis on the 12th hospital day with *S. vasiformis*at a right wrist arterial line site.[123]

Other Mucorales have been associated with a wide array of HAIs and traumatic injuries, including those associated with tornadoes, other natural disasters, and shrapnel injuries, which have been increasingly reported. In a recent review that included cases of HAIs from 1970 to 2010, the most commonly reported organs involved included skin (57 percent), the GI tract (15 percent), and the lungs (8 percent). Outbreaks have been linked to adhesive bandages, ostomy bags and other adhesive devices, wooden tongue depressors, environmental contamination during construction, nasal packing, infected donor organs, central venous catheters, urinary catheters, insulin injections, peritoneal dialysis, and steroid injections, among others.[124]

*R. oryzae*and *R. rhizopodoformis*have been described to cause cutaneous disease outbreaks related to the use of elastoplast dressings.[125]Pulmonary or sinus disease related to *Rhizopus*is more common in patients with diabetic ketoacidosis, leukemia, and lymphoma.[126]

Early clinical signs of rhinocerebral mucormycosis include perinasal cellulitis/paraesthesia, periorbital edema, mucopurulent rhinorrhea, and nasal crusting.[127]

Several studies have reported an increased occurrence of sinocerebral and pulmonary mucormycosis. Of note, there are several reports of breakthrough infections in patients receiving maintenance voriconazole therapy.[128]The treatment of choice remains ablative radical surgery and high-dose IV lipid formulation AmB (5 mg/kg/d), in some cases with adjunctive therapy with an echinocandin. A delay in therapy results in considerable mortality. Monotherapy with posaconazole has shown encouraging results in salvage studies and in combination therapy with AmB; however, this medication is typically used only after control and stabilization of the initial disease process.[129]

Trichosporon spp.

*Trichosporon*spp. are yeasts that may cause fever and positive blood cultures; they are resistant to echinocandin antifungal agents. Fifteen patients are described with *Trichosporon*isolated over a 6-year period. Five patients were infected, five possibly infected, and five colonized. All 15 patients had malignancies; 100 percent of infected patients died. No environmental cultures were positive for *Trichosporon*.[130]

Recently, an outbreak of *Trichosporon asahii*was reported in India. It involved eight neonates that developed fungemia, six of which died. The authors hypothesized that the source of the outbreak was the laminar flow unit used for preparation of IV fluids.[131]

*Fusarium*spp.

*Fusarium*is a soil and water organism that can cause skin or pulmonary lesions in immunocompromised patients. It is one of the few molds identified on standard blood culture media that is most often not a contaminant and is variably susceptible to antifungals. Risk factors for infection include tissue damage, severe immunosuppression, and receipt of a graft from a human leukocyte antigen–mismatched or unrelated donor. A common clinical presentation includes persistent fever, skin lesions, and pulmonary infection. Blood cultures are positive in 40 percent of cases, and mortality remains high at 50 to 80 percent. In immunocompetent patients, infection is often preceded by penetrating trauma, though hospital water systems have been implicated.[132]Voriconazole and posaconazole show improved susceptibility; however, resistance remains a problem.[133]

*Fusarium*spp. also not uncommonly cause corneal and eye infections, generally initiated by some type of trauma or contaminated ocular solutions.[134]Other frequent fungal causes of corneal infection include *Aspergillus*, *Curvularia,*and *Candida*spp. Topical AmB is the treatment of choice for *Candida*spp., but topical natamycin (5 percent) is used for infections with filamentous fungi.[135]

A recent multistate outbreak of endophalmitis caused by *Fusariumincarnatum-equiseti* species complex and *Bipolaris hawaiiensis*has been reported, involving 32 patients in seven states who underwent vitrectomy with epiretinal membrane peeling using Brilliant Blue G (BBG) dye, or triamcinolone injection from Franck's Compounding Lab in Florida.[136]

*Malassezia*spp.

An outbreak of *M. furfur*involving three cases within 72 hours in a NICU has also been described. Risk factors included central venous catheter, low birth weight, and lipid emulsions. Person-to-person transmission was theorized, as two HCP were colonized. However, no typing was done.[137]

*M. pachydermatis*was responsible for a cluster of eight cases of infection and colonization in a NICU over a 6-month period. Molecular typing showed that the isolates were distinct. No etiology was determined; however, risk factors for infection included indwelling catheters and parenteral lipid formulations.[138]

PHAEOHYPHOMYCOSIS (DARKLY PIGMENTED ORGANISMS)

From 1996 to 2001, 101 cases of culture-proven central nervous system infections with phaeohyphomycosis were reviewed. *Cladophialophora bantiana*was the most frequently isolated pathogen, followed by *Ramichloridium mackenziei*. Fifty percent of cases occurred in immunocompetent hosts. A recent review of phaeohyphomycosis at the M.D. Anderson Cancer Center revealed that 11 percent of isolates were responsible for invasive, often disseminated disease in severely immunocompromised hosts.[139]An aggressive medical and surgical approach is warranted, though mortality still remains high. Voriconazole has good in vitro activity and may prove to be the drug of choice for these infections.[140]

*Exophilia*spp. have also been implicated in contaminated corticosteroid injections, as described above. Improper autoclaving techniques were utilized by the compounding pharmacy. [141]Olecranon bursitis caused by *Exophilia oligospermia*has been successfully treated with aspiration and intrabursal administration of AmB.[142]

An outbreak of eight cases of *Exophilia jeanselmei*infections occurred from December 1996 through September 1997 at a hospital in Brazil. Cases were associated with neutropenia, longer duration of hospitalization, and use of corticosteroids. The patient strains genetically matched a strain recovered from deionized water used in the pharmacy to prepare solutions.[143]Finally, infection with *Alternaria*and *Phialophora*spp. has also occurred in renal transplant patients, where infection presented with dark-colored subcutaneous nodules that subsequently ulcerated.[144]In all these infections, histopathologic staining of melanin in the cell wall with the Masson-Fontana stain can be useful to establish a diagnosis.

Bipolaris spp.

As outlined above, *Bipolaris hawaiiensis*was reported as the etiological agent in an outbreak of endopthalmitis. In a cluster from an ophthalmology practice in New York, eight patients developed endopthalmitis, three of which were secondary to *Bipolaris hawaiiensis*after intraocular injection of bevanzisumab and triamcinolone.[145]

HYALOHYPHOMYCOSES: *ACREMONIUM, PENICILLIUM*(OPPORTUNISTIC LIGHTLY PIGMENTED MOLDS)

*Acremonium*has been reported to cause fungemia in immunocompromised patients, and clusters of catheter-related BSIs in a hematopoietic stem cell transplant unit have been described.[146]There is a documented cluster of four cases of eye infection after laser surgery. The cases were performed in the same operating room by different surgeons, though unfortunately no definitive source was identified.[147]

Trichophyton rubrum

Outbreaks of cutaneous disease have occurred in a geriatric hospital,[148]though invasive disease in immunocompromised patients has been reported.[149]

Rhodotorula

*Rhodotorula*spp. cause BSI in immunocompromised patients with catheters. Ten bloodstream isolates were examined for susceptibility to various antifungal agents. MICs for AmB and posaconazole were lower than those for other triazoles or echinocandins, suggesting that they may be favored agents in treatment of these unusual infections.[150]

Blastoschizomyces capitatus

Twenty-six cases of infection with this unusual pathogen from a Spanish tertiary care hematology unit were reviewed. The majority of the patients had acute leukemia and developed infection during prolonged periods of neutropenia. The majority had fungemia. Outcome was improved with prompt removal of the central venous catheter, good performance status, and early therapy. Mortality remained high at 52 percent.[151]

Conclusions

The field of mycology has recently seen major advances in therapeutic options, diagnostic tools, and strategies for the prevention and treatment of IFIs. Despite these developments, mortality remains high —especially in severely immunosuppressed patients. The number of patients at risk continues to increase with the greater number of solid organ and BMT patients, the use of corticosteroids and other immune-modulating drugs, patients with advanced AIDS, and trauma. Infections caused by *Candida*spp. are more commonly seen in the healthcare setting and are of increased epidemiologic concern. Infections and/or outbreaks caused by some of the more unusual fungi have been well documented and should heighten our awareness of the role of the environment in organism transmission.

Abstract

It is estimated that 10 percent of the population will have at least one episode of infectious diarrhea each year. Although many diarrheal diseases are self-limiting, some may be chronic and require ongoing treatment. Disease manifestations range from almost asymptomatic to severe and—in some cases—deadly. Viruses, parasites, or bacteria may be the infectious agents causing these episodes. Primary modes of transmission for most gastroenteritis agents are fecal-oral and foodborne; however, some agents may be spread from person to person. Because these agents are so different, viral agents, bacterial agents, and parasitic agents are examined in separate chapters.

Key Concepts

- Viruses are recognized as a leading cause of diarrheal disease in children.
- Rotavirus is the most common cause of severe diarrhea in children.

- Noroviruses cause the majority of viral gastroenteritis worldwide.
- Fecal-oral spread is the most common mode of transmission of viral gastroenteritis agents.
- Secondary transmission may occur with viral gastroenteritis agents.
- Acute gastroenteritis is one of the most common diseases in humans worldwide.
- Most cases of gastroenteritis resolve in 5 to 10 days.

Background

Acute gastroenteritis is one of the most common diseases in humans worldwide. Viruses are recognized as a leading cause of this disease, particularly in children.[1]Viral gastroenteritis, which can vary from asymptomatic to severe disease leading to dehydration and death, affects people of all ages, but the severity is seen in those at the extremes of age, such as children and elderly persons.[1,2,3]Viral gastroenteritis occurs in two distinct epidemiologic patterns: endemic childhood diarrhea and epidemic disease.[4]Rotavirus is the most common cause of severe diarrhea in children. However, enteric adenoviruses, astroviruses, and Sapporo-like virus exhibit a similar pattern of disease.[4]Epidemic disease is best exemplified by the norovirus; there have been outbreaks associated with astroviruses and group B rotavirus.[2,5]Other viruses that have been identified as causative agents of diarrhea include toroviruses, coronaviruses, and picobirnaviruses.

Basic Principles

CALICIVIRUS

Etiologic Agent

Human caliciviruses, members of the *Caliciviridae*family, have emerged as a major cause of viral gastroenteritis.[1,3]The two human genera, noroviruses (previously known as Norwalk-like viruses) and Sapporo-like viruses (SLVs), have been separated based on differences in genome organization, morphology, and genetic and antigenic properties.[3]These genera can be further divided into genetic clusters: the noroviruses, including the Norwalk virus (the prototype of the genus), Southampton virus, Snow Mountain agent, Hawaii virus, Toronto virus, Bristol virus, and Jena virus, and the SLVs (including the Sapporo virus [the prototype of the genus]), Parkville virus, and London virus.[1,6]The first norovirus, Norwalk virus, was named after the location of a "winter vomiting" outbreak in 1968 at an elementary school in Norwalk, Ohio.[7]The agent was finally identified in 1972 by the use of electron microscopy (EM).[8]

Noroviruses can be grouped into five genogroups (GI through GV), which are further divided into at least 34 genotypes. Human disease primarily is caused by GI and GII noroviruses, with most outbreaks caused by GII.4 strains. During the past decade, new GII.4 strains have emerged every 2 to 3 years, replacing previously predominant GII.4 strains. Emergence of these new norovirus strains has often, but not always, led to increased outbreak activity.[9]

Epidemiology

Noroviruses cause the majority of acute viral gastroenteritis disease worldwide.[10]This increased recognition of noroviruses is the result of recent availability of improved techniques to diagnose noroviruses. Human calicivirus cannot be grown in culture, and adequate viral detection methods are not always widely available; therefore, it has been difficult to establish the true burden of the disease.[2,11,12]

In addition, the epidemiology of foodborne and waterborne diseases is changing rapidly with changes in human behavior, shifts toward a global economy, industry, and microbial adaptations.[13]The recent recognition of noroviruses as a major cause of outbreaks and sporadic disease has been the result of newer norovirus-specific diagnostic techniques.[14]

Noroviruses are now recognized as the most common cause of sporadic cases of diarrhea in the community.[3,15]Outbreaks have been associated with nursing homes, schools, cruise ships, camps, restaurants, military installations, and airplane travel.[14,15]According to the Centers for Disease Control and Prevention (CDC), 348 outbreaks were reported between January 1996 and November 2000.[14]

During 2006, the CDC reported 114 confirmed norovirus outbreaks. This increase is associated with the emergence of two new cocirculating strains of GII.4. Seventy percent of these outbreaks were associated with norovirus variants (Minerva and Laurens).[16]A large proportion of these outbreaks in 2006 occurred in long-term care facilities.[16]Although outbreaks of calicivirus can occur year-round, marked seasonal patterns of outbreaks have been observed. In the northern hemisphere, norovirus-causing gastroenteritis—"winter vomiting disease"—is most common in the winter and early spring. In the southern hemisphere, outbreaks are seen most frequently in the spring/summer.[17]

CaliciNet is the outbreak surveillance network for noroviruses in the United States, launched in March 2009. From its inception to May 2010, 552 outbreaks were submitted to CaliciNet. Foodborne and person-to-person transmission were reported for 78 (14 percent) and 340 (62 percent) of the outbreaks, respectively, whereas the transmission route for the 134 remaining outbreaks was not reported. A total of 395 (72 percent) outbreaks were typed as GII.4, of which 298 (75 percent) belonged to a new variant, GII.4 New Orleans, which first emerged in October 2009.[18]More than half of all norovirus outbreaks reported in the United States occur in long-term care facilities.[19]Emergence of a new GII.4 strain, GII.4 Sydney, caused most (53 percent) of the norovirus outbreaks reported through CaliciNet during September to December 2012.[9]

Transmission

Fecal-oral spread, or aerosol formation after projectile vomiting, is the probable primary mode of viral transmission.[20,21,22]Norovirus is found in the stool and vomitus of infected persons. Primary infection results from exposure to or ingestion of a fecally contaminated vehicle, such as contaminated food or water,[11,20]whereas secondary infection results via person-to-person contact, aerosolized vomitus, fomites, and infected food handlers.[23]According to the CDC, of 348 outbreaks of norovirus from January 1996 through November 2000, the sources of outbreaks were food (39 percent), person-to-person contact (12 percent), and contaminated water (3 percent). No direct mode of transmission could be identified in 18 percent of cases.[14]

Certain characteristics of noroviruses may facilitate the spread of the virus during epidemics: low infectious dose, prolonged asymptomatic shedding, environmental stability, substantial strain diversity, and lack of lasting immunity.[20]The virus is highly infectious, and a small inoculum—as few as 10 to 100 virions—is sufficient to cause infection.[16]Infected persons can remain contagious after recovery because asymptomatic viral shedding can continue for as long as 3 weeks.[3]In addition, the virus is relatively stable in the environment. It survives freezing, heating to 60°C, and chlorine.[20]

Disease Manifestations

Typically, the average incubation period of the virus is 12 to 48 hours,[24]with gradual or abrupt development of symptoms. Patients present with abdominal cramps with or without nausea, vomiting, and diarrhea (together or alone).[12]Vomiting is often a predominant feature. Clinical symptoms for norovirus infection last a median of 5 days, and those for SLV-related symptoms a median of 6 days.[3] The duration of shedding of SLV appears shorter than that of norovirus, with SLV shedding subsiding after 14 days and norovirus subsiding 3 weeks after the onset of illness.[3]

Most patients are resistant to reinfection for 4 to 6 months; however, there is no development of long-term immunity.[12,25]Serologic studies have shown that antibodies against norovirus are obtained early in life and reach prevalence close to 100 percent at the age of 9 to 10 years.[3,26,27]It appears that the antibodies do not correlate with protective immunity in adults because symptomatic norovirus infection occurs in adults.[3]There appears to be a fraction of individuals in clinical outbreaks and volunteer studies that are unaffected by norovirus exposure. Recent serological studies indicate that individuals who are nonsecretors of blood group A and B antigens have significantly lower antibody titers to norovirus (genogroup II) than do secretors, suggesting that nonsecretors are less prone to infection or resistant to norovirus infection.[12,28]

Infections are self-limiting, and most patients recover uneventfully without sequelae. Those who are unable to maintain hydration, typically very young and elderly persons, are at risk for dehydration, resulting in electrolyte disturbances that may require hospitalization.

Diagnosis

Human calicivirus cannot be grown in culture, nor are routine laboratory tests helpful in diagnosing infection. Advances in the diagnosis of noroviruses have progressed from EM, requiring the presence of 106 virus/mL or more of stool, to the ability to detect illness using nucleic acid detection by reverse transcriptase (RT)-polymerase chain reaction (PCR).[25]

EM is most beneficial in detecting the virus from its morphological characteristics but can only be successfully used in the very early part of the illness.[6]Immunoelectron microscopy (IEM) can improve the sensitivity of EM by 10- to 100-fold.[20]In this technique, immune serum is used to enhance the detection of the virus. However, the technique is only useful for specimens collected during the early stages of disease (first 24 to 48 hours).[12,20]

The immune adherence hemagglutination assay (IAHA) was developed to allow the evaluation of Norwalk antibody levels in greater numbers of sera.[6]This test uses purified norovirus as the antigen,

and antigen/antibody complement interactions are detected by agglutination of sensitized human O erythrocytes.[6]This assay was replaced by radioimmunoassay (RIA). RIA has helped identify norovirus and related viruses as a common cause of nonbacterial gastroenteritis.

Noroviruses can be detected by enzyme immunoassay (ELISA).[20,25]This type of test can also be used to detect the presence of antibody in the infected patient by detecting a fourfold increase in immunoglobulin G (IgG) antibody titer between acute (within 5 days of onset) clinical illness and convalescence (3 to 6 weeks after acute illness). The disadvantage of the serologic assays currently available is that all antigenic types of noroviruses cannot be detected.[20]

RT-PCR assays to detect calicivirus have provided a sensitive and specific tool for noroviruses and SLV investigations. RT-PCR is the most sensitive diagnostic assay for the detection of human caliciviruses.[6]

The advantage of the sequencing assays is that they can detect the viral particles from the stools of infected patients in numbers as low as 100 particles/mL, even after the acute clinical infection has resolved. Noroviruses can be detected in stool samples stored at 4°C for several months and at –70°C for many years.[6]The major disadvantages are (1) the assays require exquisite care to prevent contamination in the laboratory and (2) few laboratories are equipped to perform these analyses.[14]In addition, the available primers for RT-PCR assays detect multiple strains of calicivirus, and other strains can escape detection.[6]Thus, this technique is used primarily for epidemic outbreak investigations. RT-PCR and EIA have been used together to identify and quantify noroviruses with some success.[29]

Treatment

Treatment of human calicivirus infection is symptomatic, and its aim is to prevent or treat the dehydration secondary to the disease.[25]It is important to start liquid intake early to correct the water deficit that is often associated with vomiting and diarrhea. Rarely, parenteral intravenous therapy may be required. Currently, there are no vaccines for calicivirus.

Infection Prevention and Public Health Concerns

Noroviruses are highly contagious, with a low infectious inoculum of less than 100 viral particles[20]; therefore, interruption of transmission is extremely important. Direct spread from person to person from handling contaminated secretions or objects becomes important in outbreaks involving a closed environment, such as day care centers, nursing homes, and cruise ships.[5]Even inhalation of aerosolized infectious secretions has been implicated for person-to-person spread, especially in closed environments when an obvious common source of water or food cannot be readily implicated.[23]

To implement infection prevention measures, it is important to identify the etiologic agents involved in a viral infection outbreak. Noroviruses are able to survive in water and are relatively resistant to chlorination.[20]Thus, fecal contamination of large bodies of water used for drinking or recreational activities, such as swimming pools, may serve as the prime source of an outbreak. Shellfish, which are filter feeders, are efficient in concentrating the microbes from contaminated water.[12,20,25]The virus does not replicate in food as many bacteria do and is destroyed by thorough cooking. Ingestion of inadequately cleaned and cooked shellfish or fresh salads washed in contaminated water is often

implicated in large foodborne outbreaks, as are food handlers with symptomatic or asymptomatic norovirus infection.[12]

Noroviruses have a very short incubation period and are highly infectious; therefore, any patient with undiagnosed acute gastroenteritis is best placed in appropriate precautions. It is essential that strict attention be paid to hand hygiene with use of soap and water before and after contact with the patient and/or inanimate objects that can be contaminated. It is also necessary to clean all surfaces with suitable disinfectants.[1,20,25]

Secondary transmissions are a concern.[30]For example, prevention of food contamination during preparation requires that food handlers maintain strict personal hygiene at all times. Ill workers should be excluded from food handling, and food preparers should minimize direct contact with ready-to-eat foods.[31]Keeping the spread of virus from being introduced into healthcare settings is difficult, and some advocate closing affected units to new patient admissions, excluding affected staff from work for 48 hours after recovery, and rigorous disinfection as key features of control.[32]

Outbreaks of norovirus have been traced to contaminated municipal drinking water, well water, lakes, swimming pools, and commercial ice.[20]In one recent study, it was estimated that 12 to 16 percent of norovirus gastroenteritis was introduced by contaminated food or water.[33]Methods that prevent sewage/fecal contamination of large bodies of water are less effective due to the inability to assay water for the presence of noroviruses and because of the relative resistance of the noroviruses to chlorination.[34]It is important to implement safeguards, including changes in tracing, screening, and recall of contaminated food products; closing of contaminated oyster beds; restricting elapsed time before previously infected people can return to work; and timely prevention and control measures in healthcare settings.[35]

When it is not possible to get laboratory confirmation of norovirus, the CDC recommends that health departments use Kaplan criteria to determine if an outbreak was possibly caused by the norovirus. There are four components of the Kaplan criteria: (1) a mean (or median) illness duration of 12 to 60 hours, (2) a mean (or median) incubation period of 24 to 48 hours, (3) more than 50 percent of people with vomiting, and (4) no bacterial agent found in stool culture. When all four are present, it is very likely that the outbreak was caused by norovirus. However, about 30 percent of norovirus outbreaks do not meet these criteria. If the criteria are not met, it does not mean that outbreak was not caused by norovirus.[36]

ROTAVIRUS

Etiologic Agent

Rotavirus is a member of the *Reoviridae*family that causes gastroenteritis in infants and young children. Intact virus particles resemble a wheel with spokes and a rim when viewed by EM.[37]Rotaviruses exhibit great diversity. They exist in seven distinct serogroups, A through G, that differ antigenically, though human pathogens belong to groups A, B, and C.[38]Among the human pathogenic rotaviruses, at least 42 different serotype combinations have been identified; however, four serotype combinations (G1-G4) are predominant worldwide, representing more than 90 percent of infections.[39]

Epidemiology

In both developed and developing countries, almost all children are infected with rotavirus by 2 to 3 years of age.[37]It is the most common cause of severe dehydration among children worldwide, with a death rate of approximately 527,000 annually among children under 5 years of age with diarrhea as of 2004.[40]Each year in the world, approximately 111 million episodes are the cause of 25 million clinic visits and 2 million hospitalizations in children under 5 years of age as of 2000.[41]In the United States, during the prerotavirus vaccine era, four of five children were symptomatic for rotavirus gastroenteritis, one in seven required a clinic or emergency department visit, one in 70 was hospitalized, and one in 200,000 died from rotavirus infection, within the first 5 years of life.[42]The maximum incidence occurs in infants from the ages of 6 to 24 months, which correlates with the time that maternal antibody titers decline.[37] Whether or not breast-feeding protects infants from rotavirus diarrheas is unclear.[37]

Asymptomatic infection can also occur. Adults can be afflicted with symptomatic rotavirus infection, but the disease course is usually mild.[43]It is occasionally reported as the cause of traveler's diarrhea[44]and diarrhea caused among healthcare personnel.[45]Rotavirus has been detected as a cause of gastroenteritis among adults residing in aged-care facilities in 13 percent of outbreaks.[46]However, the highest incidence in adults is in parents of infected children.[47]

In temperate climate zones, seasonal pandemics are observed of repeatable onset and duration with a peak of cases in the cooler months of each year.[37]In tropical climates, seasonality is less pronounced, yet infection remains most common in the cooler and drier times of the year.[37]Dry weather may promote transmission, as the rotavirus particle is inactivated more quickly in conditions of relatively high humidity.[37]

Transmission

Virus transmission occurs primarily through the fecal-oral route but can also occur through close person-to-person contact[48,49]and through fomites.[49,50]Although rotavirus has been shown to reside in other locations, such as the urine and upper respiratory specimens, transmission has not been associated with its presence in these locations.[51]The reservoir for rotavirus is not fully understood; however, infected infants shed virus for a period of 4 to 10 days.[37]Community-wide outbreaks of rotavirus attributed to fecally contaminated water and perpetuated by person-to-person transmission have been reported but are uncommon.[52,53]

Disease Manifestations

Rotavirus infects and replicates in the villous epithelial cells lining the small intestine.[54,55]The mechanism by which rotavirus causes diarrhea is not well understood, though studies have suggested a variety of mechanisms, including reduction in absorptive surface, stimulation of intestinal secretion of fluids, impaired absorption, and endotoxic effects from the NSP4 protein, which is secreted by rotavirus.[37]The most common presentation among children begins with fever and vomiting for 2 to 3 days, followed by a nonbloody diarrhea.[56]Vomiting is more common and prolonged with rotaviral gastroenteritis than most

other causes of pediatric gastroenteritis.[56]Diarrhea is usually profuse, with as many as 20 bowel movements per day, which causes an isotonic dehydration. Patients with syndromes that include profuse vomiting are at risk for the most severe dehydration. Repeat bouts of rotavirus gastroenteritis are usually less severe than initial disease.[57]Gastrointestinal symptoms are often preceded by cough and coryza, though the presence of the virus within cells of the respiratory system has not been shown to affect the spread of the virus.[56]Rotavirus is not usually associated with fecal leukocytes, but fecal leucoycytosis has been reported.[37]

In adults, rotavirus causes a wider spectrum of manifestations, making it difficult to describe a typical clinical presentation. Studies in normal, healthy adult volunteers subjected to rotavirus ingestion have yielded an onset of illness that is typically 2 to 6 days, with a duration of 1 to 5 days.[58,59]Symptoms in these adult studies most frequently consisted of diarrhea, headache, fever, nausea, malaise, and abdominal cramping.[58,59]

Children with immunodeficiencies may have rotavirus-induced chronic diarrhea.[37]Immunocompromised patients are at risk for sustained symptoms and dissemination of rotavirus.[37]Rotavirus infections in patients with human immunodeficiency virus (HIV) cause a chronic diarrhea and can be associated with recurrence in this patient population.[60]

Rotavirus-specific immunoglobulin M (IgM) is evident in serum and duodenal fluid.[61]Stool immunoglobulin A (IgA) titers peak at 14 to 17 days after initiation of disease but remain detectible for greater than 1 year.[62]Although the antibodies produced will cross-react with subsequent rotavirus infections, initial antibody responses are serotype specific and do not confer lifelong immunity.[63]

Diagnosis

There is no identifying symptomatology associated with rotavirus-induced acute gastroenteritis. Diagnosis requires identification of the etiologic agent from fecal matter or rectal swabs. A commercially available enzyme-linked immunosorbent assay (ELISA) is commonly used to test specimens for rotavirus antigen.[64]Latex agglutinin kits are also available but are somewhat less sensitive than other methods.[64]

Commercial assays are directed at group A rotaviruses and do not detect nongroup A rotavirus types.[58,64]Because bacterial pathogen detection in stool specimens yields a low sensitivity, it has been postulated that testing stool for rotavirus antigen could be a very cost-effective practice.[58]However, the fact that adults do not shed as much virus as children when infected could influence this practice in older patient populations. More sensitive methods have been developed, including PCR, which is up to 1,000 times more sensitive than detection with ELISA.[65]PCR is currently used in epidemiologic studies and allows determination of P and G types and permits more definition of strain differences.[37]

Treatment

Fluid and electrolyte replacement with early nutritional support are the main focuses of treatment for self-limiting diarrheal conditions, in addition to providing symptomatic relief to infected patients. Two phases of treatment are recommended by the CDC: rehydration and maintenance.[66]Oral rehydration

solutions of reduced osmolarity are indicated in the treatment of mild to moderate dehydration. An initial rapid rehydration should occur, over 3 to 4 hours.[66]

Infants should continue breast-feeding on demand even during acute rehydration. Older children should resume age-appropriate unrestricted diets, including complex carbohydrates, meats, yogurt, fruits, and vegetables; foods high in simple sugars should be avoided.[66]Early feeding decreases changes in intestinal permeability caused by infection,[67]reduces illness duration, and improves nutritional outcomes.[68]

Antibiotics and antisecretory agents are not indicated; however, antidiarrheals such as loperamide and diphenoxylate can be used to help control diarrhea, but these agents are rarely used in children.[66]Oral hydration solutions are effective in treating dehydration related to rotavirus gastroenteritis, even in the presence of moderate vomiting, and are preferred over intravenous rehydration.[37,66]

If oral rehydration is not successful and symptoms of dehydration persist, intravenous fluids and hospital admission may be needed. Oral doses of human serum immunoglobulin are not indicated for routine use but may have a role in treating chronic rotavirus diarrhea.[37]Oral immunoglobulin has been shown to be successful in decreasing the duration of illness in several patient groups, including immunocompetent and immunocompromised children, as well as adults undergoing bone marrow transplantation.[69,70]

Prevention by immunization is a critical approach to decreasing the impact of rotavirus infection. Currently there are two licensed vaccines available in the United States: RotaTeq and Rotarix.[37]RotaTeq is a pentavalent human-bovine (WC3) reassortant live-attenuated, oral vaccine developed by Merck Research Company.[38]RotaTeq contains four live reassortant rotaviruses (G1, G2, G3, and G4) and an attachment protein (P7).[38]In two phase III trials, the efficacy of RotaTeq against rotavirus gastroenteritis of any severity after completion of a three-dose regimen was 74 percent and against severe rotavirus gastroenteritis was 98 percent.[38]RotaTeq was licensed in February 2006 by the U.S. Food and Drug Administration (FDA) for use among infants in the United States and is routinely recommended as a three-dose schedule at 2, 4, and 6 months of age.[61]Rotarix, a live-attenuated human rotavirus vaccine, is an oral vaccine developed by Avant Immunotherapeutics and licensed to GlaxoSmith Kline Biochemicals, who further modified the strain.[38]Rotarix has been tested in 11 Latin American countries and Finland in phase III trials on more than 63,000 children. In a subset efficacy trial, the vaccine demonstrated a protection rate of 85 percent against severe rotaviral gastroenteritis and 100 percent protection against the most severe dehydrating rotaviral disease.[38]Rotarix was licensed in April 2008 by the FDA for use among infants in the United States and is routinely recommended as a two-dose schedule at 2 and 4 months of age.[71]

A CDC report indicates that there was delayed onset and diminished magnitude of rotavirus activity during the 2007 to 2008 and 2008 to 2009 seasons in the United States when compared with the median during 2000 to 2006. This appears to coincide with increasing use of rotavirus vaccine (RotaTeq) among infants during that time period.[72]

Although the CDC reported that the 2008 to 2009 season had 15 percent more positive rotavirus test results than the 2007 to 2008 season, the number of positive test results during each season remained substantially lower (60 to 64 percent lower) than the median observed during 2000 to 2006.[72]Figure 79A-1 depicts this decrease as well as the delayed onset of the 2007 to 2008 season, by 11 weeks, and the 2008 to 2009 season, by 6 weeks.[72]

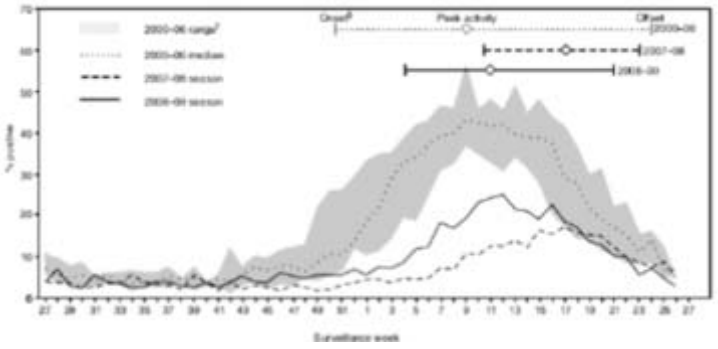

Figure 79-1. Percentage of rotavirus tests with positive results, by surveillance week from participating laboratories, National Respiratory and Enteric Virus Surveillance System (NREVSS), United States, July 2 View Image

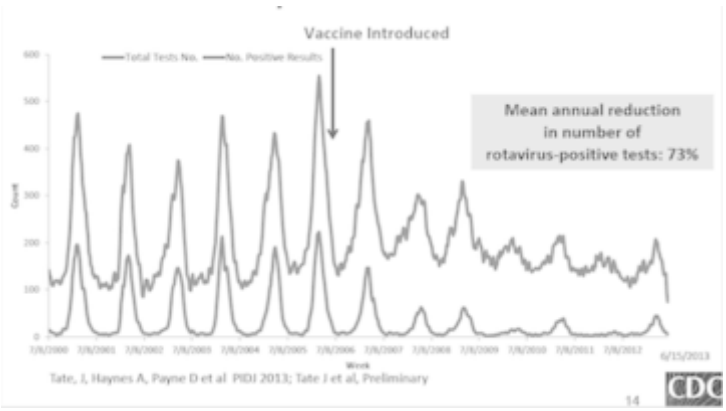
* A median of 67 laboratories (range: 62 to 72) contributed rotavirus testing data to NREVSS during July 2000 to June 2009.
† Range created using the maximum or minimum percentage of rotavirus-positive tests for each surveillance week during 2000–2006. Maximums and minimums for each week might have occurred during any of the six rotavirus seasons during 2000–2006.
§ The onset of rotavirus season was defined as the first of two consecutive weeks during which the percentage of stool specimens testing positive for rotavirus was ≥10 percent; offset was defined as the last of two consecutive weeks during which the percentage of stool specimens testing positive for rotavirus was ≥10 percent.

Figure 79A-1. Percentage of rotavirus tests with positive results, by surveillance week from participating laboratories, National Respiratory and Enteric Virus Surveillance System (NREVSS), United States, July 2000–June 2009.*[72]



The 2009 to 2010 season had a decline in positive rotavirus tests. The 2010 to 2011 season was eight weeks shorter than the prevaccine baseline. During the 2011 to 2012 season, the starting threshold was never achieved nationally.[73]During these last two seasons, there was a 74 to 90 percent reduction nationwide in the number of positive rotavirus tests compared to the prevaccine baseline. In addition, the number of tests performed declined annually 28 to 36 percent in the same period.[73]During the five postvaccine seasons from 2007 to 2012, a biennial pattern of increases in rotavirus activity occurred, still remaining substantially below prevaccine levels.[73]

Preliminary data presented by the CDC at the Association for Professionals in Infection Control and Epidemiology (APIC) meeting in June 2013 demonstrate a 73 percent mean annual reduction in number of rotavirus-positive tests compared to the prevaccine levels in the United States, as seen in Figure 79A-2.[74]

Figure 79-2.

Rotavirus tests at reporting laboratories, number of tests and number rotavirus-positive July 2000–June 2013.[74]

View Image

Some postmarketing studies have demonstrated a small risk of intussusception for infants from the two rotavirus vaccines.[75]The CDC's Vaccine Information Statement summarizes these and indicates that the risk of intussusception from rotavirus vaccination ranges from about 1 in 20,000 U.S. infants to 1 in 100,000 U.S. infants after vaccination. This risk is highest within a week after the first or second vaccine dose.[62]

This small increased risk of intussusception is outweighed by the benefits of rotavirus vaccination.[75]

Infection Prevention and Public Health Concerns

Rotavirus transmission can be avoided by limiting exposure by the fecal-oral route. Contact with contaminated food and water should be avoided. Rotavirus survives in the environment on hard surfaces, in water supplies, and on the hands of humans.[76]Because a large proportion of virions survive on human hands for more than 60 minutes, hand washing is essential to the prevention of spread. Patients identified as infected should be placed in Contact Isolation during inpatient visits because of continuous fecal shedding. Infants infected with rotavirus shed the virus in high concentrations in the feces for as long as 7 days after onset of gastroenteritis.[37]Particular attention should be given to ensure handling of diapers in a proper manner.

Common hand-washing agents and disinfectants do not affect rotavirus, but 70 percent ethanol and chlorine-containing solutions are effective.[76]A human challenge study found the following compounds effective in interrupting transfer of rotavirus from stainless steel to a finger: a disinfectant spray (0.1 percent orthophenylphenol and 79 percent ethanol), sodium hypochlorite (800 ppm free chlorine), and a phenol-based product (14.7 percent phenol diluted 1:256 in tapwater). Quaternary ammonium product (7.05 percent quaternary ammonium compound diluted 1:128 in tap water) and tap water did not stop the spread of rotavirus.[77]

Well water can become contaminated with rotavirus. Killing or inactivating the virus requires boiling the water at a rolling boil for 1 minute; a point-of-use filter will not remove it.[78]

For infection control at the population level, routine infant rotavirus immunization is making a significant public health impact in infants.[75]In response to an outbreak of rotavirus gastroenteritis, postexposure vaccine prophylaxis is not a recommended strategy.[42]

ASTROVIRUSES

Etiologic Agent

Astroviruses are members of the family *Astroviridae*and are recognized as an important cause of gastroenteritis in adults and especially children.[79]Under EM, astroviruses have a characteristic five- or

six-pointed star visible on some particles.[79]There are eight established genotypes corresponding with eight serotypes, with serotype 1 being the predominant serotype in most studies.[79]

Epidemiology

Astroviruses are found worldwide[80,81]and have been detected in diarrheal stools of children brought to medical attention in a variety of settings, including schools, daycare settings, and pediatric wards.[1,81]In hospital-based studies, rates of 2 to 16 percent were detected and in community-based studies rates of 5 to 17 percent were detected.[66]The viruses have also been found to cause illness in adults and immunocompromised patients, such as transplant patients and HIV-infected individuals.[82,83]

Seroprevalence studies in the United States and elsewhere have demonstrated the presence of astrovirus antibodies in more than 90 percent of children by 9 years of age,[84]suggesting that infection, largely asymptomatic, is common.[79]

Transmission

Transmission of astrovirus is presumably by the fecal-oral route, and there have been associations with consumption of sewage-polluted shellfish and ingestion of water from contaminated sources.[79,85,86]The virus has been demonstrated to survive on inert surfaces long enough to suggest that fomites could play a role in secondary transmission.[85]

Disease Manifestations

The predominant symptom of astrovirus gastroenteritis is watery diarrhea; however, nausea, headache, malaise, and low-grade fever may occur; vomiting occurs less commonly.[79]In general, the symptoms are similar to those seen in rotavirus-infected children, but they are milder. The incubation period is approximately 3 to 4 days.[79]Disease manifestations usually last 5 days or less when coexisting pathogens are not present.[79]The duration of virus shedding, as assessed by PCR, may be a long as 35 days.[79]The pathogenesis of the disease induced by astrovirus has not yet been established.[1]

Symptomatic disease occurs mainly in small children and elderly persons, which suggests a reduction in antibodies throughout the process of aging, but the determinants of immunity are not well known.[1]The fact that astrovirus has been associated with outbreaks of disease in older children and adults suggests that immunity to disease may be overcome by larger-than-normal inocula of infectious spread by atypical vehicles of infection.[4]

Diagnosis

Unlike other viral agents of gastroenteritis, astroviruses are often shed in large amounts in stool and can be readily detected by EM.[79]Detection of astrovirus in cell culture has been carried out by IEM or immunofluorescence.[79]An ELISA was developed in the 1990s and was found to have comparable sensitivity (91 percent) and specificity (98 percent) to IEM.[87]Reverse-transcriptase PCR is even more sensitive in detecting astrovirus.[79]Genotyping of the virus is also available.[4]

Treatment

Treatment of viral gastroenteritis caused by astroviruses is supportive, if needed. Treatment is similar to that of other viral gastroenteritis: prevent or treat the dehydration secondary to disease.[79] Fluid and electrolyte replacement with early nutritional support are the main focuses of treatment for self-limiting diarrheal conditions.[66] Illness is generally self-limited.

Infection Prevention and Public Health Concerns

Interruption of transmission of the infection is important, especially in hospitals and centers that care for small children. Therefore, it is essential to reinforce hygiene measures and clean all surfaces with suitable disinfectants.[1] Viruses from the gastrointestinal tract, including astrovirus, persist for approximately 2 months on surfaces. This can be a continuous source of transmission; reinforcing the importance of regular preventive surface disinfection.[88]

ENTERIC ADENOVIRUSES

Etiologic Agent

Human adenoviruses were first isolated from adenoid tissues in 1953 and named for the tissue of its origin.[89] It is a nonenveloped icosahedral virus containing a 36-kb, double-stranded DNA genome. The *Adenoviridae* family is divided into five genera; those causing disease in humans are categorized into the *Mastadenovirus* genus.[90] The human mastadenoviruses are further divided into six subgenera (A through G) and 53 serotypes on the basis of antigenicity.[91] The serotypes 40 and 41 of subgenus F account for most cases of gastroenteritis in children. Serotypes 31, 12, and 18 of subgenus A and serotypes 1, 2, 5, and 6 of subgenus C have been identified as causative agents for gastroenteritis.[1,92]

Epidemiology

Enteric adenovirus infection occurs worldwide and has been associated with as many as 15 percent of cases of gastroenteritis in children.[93,94] It is considered to be the second most common cause of viral gastroenteritis, next to rotavirus.[94] Enteric adenovirus primarily affects children younger than 4 years, with very little seasonal variation.[95] Enteric adenovirus has been recognized as a causative agent of gastroenteritis in transplant recipients (both stem cell and solid organ)[96] as well as patients with AIDS.[97]

Transmission

Adenovirus is spread through droplet or fecal-oral transmission from individuals with acute infection or asymptomatic viral shedding postinfection.[92] Adenoviruses 40 and 41 are shed in feces in large numbers. They are frequently found in fecally polluted waters and have been detected in shellfish but have not been apparently associated with foodborne illness.[98] Fecal-oral transmission does account for sporadic diarrheal illness in children.[99] Convincing evidence of donor organ-associated transmission of adenovirus is supported by observations noting that infection often occurs early after transplantation and often involves the donor organ (e.g., lung or intestine).[96]

Disease Manifestation

A distinctive feature of enteric adenovirus infection is protracted diarrhea. The incubation period of 8 to 10 days is longer than that for other viral gastroenteritis,[73] as is the duration of diarrhea. Diarrhea may be associated with fever or vomiting and may last as long as 2 weeks.[92] The illness is generally mild and self-limited; however, it can be severe and persistent in immunocompromised hosts.[93,100] Adenoviruses are highly immunogenic and confer type-specific immune responses that result in lifelong protection.[101]

Diagnosis

Enteric adenoviruses (serotypes 40 and 41) cannot be cultured on standard human tissue culture cells. They require the culture cells transformed by adenovirus.[92] Diagnosis is usually made by ELISA, especially for serotypes 40 and 41 in stool samples. Serotypes can be identified by neutralization and hemagglutination inhibition assays or PCR.[93] PCR has become widespread due to greater sensitivity, specificity, and rapid turnaround.[92]

Treatment

Enteric adenovirus infection usually resolves without specific therapy. Treatment is supportive, as with other viral gastroenteritis.

Infection Prevention and Public Health Concerns

Contact and Droplet Precautions in addition to Standard Precautions should be practiced. Infected workers should not work until symptoms have resolved.[99] There is no vaccine available for the general public, nor any targeting of the types most likely to cause gastrointestinal disease. But as of 2011 a new live, oral vaccine against adenovirus types 4 and 7 is available to U.S. military personnel who are 17 to 50 years of age. It is administered to military recruits entering basic training in order to prevent acute respiratory disease.[102]

TOROVIRUSES

Although toroviruses are among the established agents of gastroenteritis in animals, the role in diarrheal illness in humans remains to be elucidated.[103] The few controlled studies have shown that torovirsuses have a more consistent association with illness than enteric coronaviruses.[104]

Their associations with neonatal necrotizing enterocolitis, healthcare-associated gastroenteritis, and acute and persistent diarrhea in children have been reported.[103,105,106,107] A 2012 study using direct EM reported finding toroviruses as the most commonly identified cause of healthcare-associated infection at the Hospital for Sick Children in Toronto, Canada.[107]

CORONAVIRUSES

Enteric coronaviruses have been most frequently associated with gastroenteritis in neonates, infants, and patients with AIDS.[104] However, their significance as causative agents of gastroenteritis was unclear until 2002, when the severe acute respiratory syndrome (SARS) outbreak occurred in China. SARS-coronavirus caused significant gastrointestinal disease. In one Hong Kong outbreak, a total of 38.4 percent of patients with SARS-coronavirus developed diarrhea, and some presented with fever and gastrointestinal symptoms only.[93,108] The diarrhea was usually mild, and no deaths were attributed to the

gastroenteritis.[108] In the Toronto outbreak, 23.6 percent of the 144 patients had diarrhea on presentation.[109] Rigorous application of hospital infection control procedures, particularly Contact and Droplet Precautions, provided a strong beneficial effect on the spread of the SARS coronavirus.[110]

PICOBIRNAVIRUSES

Picobirnaviruses have been implicated as a cause of gastroenteritis in immunocompromised hosts.[111] Their role as causative agents in normal hosts is unclear because the prevalence of the viruses in fecal specimens of individuals with or without diarrhea was similar.[79] Evidence for genetic relatedness between human and animal viral strains has been found; suggesting extant crossing points in the ecology and evolution of heterologous viral strains.[112]

APIC TEXT OF INFECTION CONTROL AND EPIDEMIOLOGY

Herpes Virus

Author(s): John Anthony Zaia, MD
Professor and Chair, Department of Virology

Beckman Research Institute, City of Hope Medical Center
Duarte, CA

Published: October 3, 2014

Abstract

The Herpesviridae family is large and found among all vertebrates. The viruses share a common structure and a common biology consisting of a chronic intermittent infection fluctuating between low-level activity (latency) and high-level replication (reactivation). There are eight known herpesviruses of humans, and these form three subfamilies (the alpha-, beta-, and gamma-herpesviruses) that have laboratory and clinical features in common. These characteristics range from rashes to malignancies. The methods for prevention and treatment of these infections are discussed in this chapter.

Key Concepts

- The herpesviruses are among the 1.7 million healthcare-associated infections that occur annually in hospitals in the United States. Breaches in infection prevention protocols and lack of pathogen-specific education on transmission, disease presentation, and prevention matters are major contributing factors. Immunocompromised and young individuals are at greatest risk. Implementing and adhering to Standard, Contact, and Droplet Precautions can reduce these numbers.
- The herpesviruses are a family of eight DNA viruses that initiate acute, chronic, and latent infections of the skin, epithelial cells, lymphocytes, and neurons. These include herpes simplex type 1, herpes simplex type 2, varicella-zoster virus, Epstein-Barr virus, cytomegalovirus, human herpesvirus 6, human herpesvirus 7, and human herpesvirus 8.
- Herpesviruses are transmitted by close intimate contact or exposure to virus-containing body fluids (saliva, urine, blood, breast milk, and contaminated respiratory or genital secretions). Exposure and first infections are acquired in childhood.
- Each herpesvirus has a preferred tissue target, but infections usually present as generalized or local infections of neonates, young children, healthy adults, and immunocompromised patients.

- After initial infections, latency may be established in tissues or neurons and reactivate in response to stress, infections, medications, sunlight, or surgery.
- Most infections are asymptomatic. Active disease may present as virus-filled blisters on the face or genitals, fever, malaise, sore throat, rash, or tumors.

Background

Viruses are named and organized into groups, or families, based on their physical properties and their growth patterns relative to specific hosts or organ tissues. The family of viruses called Herpesviridae has more than 100 members, is represented across the wide range of vertebrate animals, and is even found in some mollusks. There are few genetic similarities between herpesviruses of lower vertebrates compared with those of higher animals, but because they look alike by electron microscopy, these widely differing viruses are all members of the same family. The appearance that makes each of them a herpesvirus is the presence of a double-stranded DNA core, an icosahedral capsid, a tegument layer between the capsid and the envelope, and a bilipid membrane envelope (see Figure 80-1). For the vertebrate species that are more closely related, their herpesviruses are also somewhat similar and can share cross-reacting antigens. Yet, with some exceptions, the herpesviruses are very species-specific and do not replicate or produce disease outside a limited host range. For example, the herpesviruses of catfish do not infect humans. However, as species become closer, there is not only the similarity of virus genes but also the potential for cross-species infection and disease. Thus, herpesvirus simiae of Cercopithecine monkeys shares proteins with human herpesviruses and is a serious pathogen in man.

Structure of a herpesvirus.

View Image

The primary infection may or may not produce a serious disease, but during this initial infection, there can be an "escape" from normal immune surveillance, with certain viruses more effective at this than others. The result is the ability of the virus to survive for the lifetime of the animal. When virus infection subsides, which is associated with a limitation of the gene expression ("latency"), there is cessation of virus replication or a profound reduction in virus growth. Herpesvirus latency is the state of virus infection in which there is no significant virus replication. In practical terms, latency appears to be due to a functional absence of sufficient cellular transcription factors for permissive replication. Because cells vary in states of transcriptional activation, the ability of the virus to replicate and be detected alternates between latency and reactivation. Herpesvirus reactivation is the renewal of virus replication in cells that previously have been infected with that specific herpesvirus. Thus, herpesviruses have the ability to remain in selected tissues of the host, for example, in nerve, breast, or salivary tissue or in lymphoid organs. When reactivation occurs, disease syndromes can occur that are different from the primary infection. Thus, reactivation of herpes simplex type 1 (HSV-1) causes a fever blister; varicella-zoster virus (VZV) can cause shingles; cytomegalovirus (CMV) can cause retinitis; and Epstein-Barr virus (EBV) can cause lymphoid proliferation and malignancy.

Despite the relative lack of serious disease in the healthy individual, it has become recognized that the immune system works overtime to control these latent infections. For example, for CMV and EBV, it is not unusual to find asymptomatic adults with 10 percent or more of total T lymphocytes committed to control of these infections.

When the immune system is immature, fails, or is purposely altered during cancer or other therapies, there can be serious infections with these viruses. For example, there can be dissemination of HSV-1 and CMV in the newborn, CMV retinitis in patients with acquired immunodeficiency syndrome (AIDS), EBV lymphoproliferative syndromes after organ transplantation, and other serious manifestations of these herpesvirus infections that are not seen in persons with an intact immune system. These viruses may vary in infection patterns and in disease presentation, but the seriousness of the resultant diseases is such that it is important to be familiar with the spectrum of human herpesvirus infection and pathogenesis.

This chapter reviews the important aspects relating to the understanding of the herpesviruses of humans and focuses on the relative differences among these viruses, their diagnoses and treatment, and the current methods for their control.

Basic Principles

CLASSIFICATION

There are eight herpesviruses that have been isolated from humans; each has a numerical designation and a common name, which will be the preferred terminology in this chapter. This terminology and certain of the distinguishing clini-cal characteristics of these eight viruses are shown in Table 80-1.

Table 80-1 The Human Herpesviruses

Virus	Population Frequency[a]	Age at Infection	Clinical Disease	Antiviral Therapy	Prevention	
HSV-1	HHV1	50%–60%	Infancy Childhood	Gingivostomatitis Keratitis CNS (rare)	Yes	Contact Control
HSV-2	HHV2	15%–25%	Adolescence Young Adults	Genital infection Meningitis	Yes	Contact Control
VZV	HHV3	95%	Childhood	Skin vesicles Zoster	Yes	Vaccine & Contact Control

EBV	HHV4	75%	Childhood Adolescence	Mononucleosis B-cell lymphoma Hodgkin lymphoma NP carcinoma Hairy leucoplakia	No	Contact Control
CMV	HHV5	60%	Fetus/infants Children Young Adults	Birth defects CNS/eye Pneumonia Enteritis	Yes	Contact Control
HHV-6	HHV6	90%	Infancy	Roseola Encephalitis	Yes	Unknown
HHV-7	HHV7	90%	Infancy	Roseola	No	Unknown
KSHV	HHV8	1%–5%	Variable	Kaposi's sarcoma Primary effusion lymphoma Multicentric Castleman disease	No	Contact Control

[a]The frequencies are shown for a Western country and will vary with living conditions (i.e., social crowding and poverty). HSV, herpes simplex virus; VZV, varicella zoster virus; EBV, Epstein-Barr virus; CMV, cytomegalovirus; HHV, human herpesvirus; KSHV, Kaposi's sarcoma herpes virus; CNS, central nervous system; NP, nasopharyngeal.

SIMILARITIES AND DIFFERENCES AMONG THE HERPESVIRUSES

Although the herpesviruses look alike, they demonstrate a wide range of biologic and clinical differences, and these differences are used to further divide them into subfamilies. The further classification of the herpesviruses is based primarily on the biologic behavior of the virus in tissue culture, and this permits a division into three subfamilies, called Alphaherpesvirinae, Betaherpesvirinae, and Gammaherpesvirinae. The alpha-herpesviruses—HSV-1, HSV-2, and VZV—have a wider range of infection than do other herpesviruses, including a more rapid and lytic infection and lack of persistence of infection in vitro. CMV, HHV-6, and HHV-7 are beta-herpesviruses that grow more slowly in culture, are cell associated but still lytic, and share common protein sequences. EBV and Kaposi's sarcoma-associated herpesvirus (KSHV) are gamma-herpesviruses that, though lytic at times, can grow

productively in vitro and in vivo by immortalizing the infected cells and by supporting cellular proliferation. These gamma-herpesviruses contribute to genetic instability and multistep tumorigenicity.

EPIDEMIOLOGIC PRINCIPLES OF THE HERPESVIRUSES

These viruses are generally acquired in childhood and, except for the alpha-herpesviruses, there is often no significant disease associated with primary infection. From time to time, the virus can reactivate and become infectious, usually in specific body fluids. These viruses can exist in an immune population and be transmitted after reactivation to nonimmune persons. Reactivation allows release of infectious virus days, months, or years after initial infection and even at times when the host shows no sign of disease.

Although disease is usually mild in immunologically healthy persons, each of these viruses can produce life-threatening infection in immunosuppressed persons. Much of the prevention and treatment of these viruses is directed to the control of herpesviruses in this population. Hematopoietic stem cell transplantation (HSCT) and solid organ transplantation (SOT) are continually expanding fields of medicine with increasingly novel methods for limiting the natural host community. As a consequence, new and unusual presentations for herpesvirus infections have occurred. In the earliest HSCT experiences, CMV was the significant pathogen producing a previously unrecognized syndrome of fever and interstitial pneumonia. With T-cell-depleted HSCT and SOT, EBV was observed to produce a posttransplant lymphoproliferative disease. The viral etiology of Kaposi's sarcoma (KS) in AIDS has been shown to be due to KSHV, and this virus is also a problem in transplantation medicine.

Specific Herpesviruses

HERPES SIMPLEX VIRUSES TYPE 1 AND TYPE 2

Nature of HSV-1 and HSV-2

The alpha-herpesviruses, HSV-1 and HSV-2, are distinct viruses based on antigenic and genetic composition, but they are considered together here because of the similarity of disease presentation and epidemiology. They were first noted to be different in subtle tissue culture growth patterns and were separated by serologic means into a type of virus usually isolated from oral specimens (HSV-1) and a type usually isolated from genital specimens (HSV-2). HSV-1 and HSV-2 share about 50 percent of their genetic sequences, and both can infect and replicate in cutaneous tissues such as skin and mucous membranes, enter into the adjacent sensory nerve fibers, and move up the nerve to the cell nucleus, where they can become latent in cell bodies or ganglia of the central nervous system (CNS). Upon reactivation, the virus can return to the cutaneous distribution area of the infected nerve to appear as "recurrent herpes."

Epidemiology of HSV-1 and HSV-2

Humans are the only natural reservoir for HSV-1 and HSV-2, and spread is solely via human-to-human contact with infected material, usually from mucous membranes or skin. The virus does not spread by aerosol, and it is unlikely to be spread by fomites due to its lability. The differing epidemiologic patterns of these two viruses are due to the sites of infection from which they are transmitted. HSV-1 is usually an oral infection, known as herpes labialis or herpes gingivostomatitis, and spreads in early childhood via infected saliva and skin. This also accounts for high endemic levels of HSV-1 infection in areas of close contact and crowding, such as socioeconomically depressed areas, and for high rates of new infection in situations associated with close contact, for example, college dormitories. HSV-2 is usually a

genital infection, known as herpes genitalis, and spreads by sexual contact. Because HSV-1 infection usually precedes HSV-2 infection and because there is some protection afforded by HSV-1 immunity, the primary infection with HSV-2 can be asymptomatic. Only 10 percent of HSV-2-seropositive individuals report a history of herpes genitalis. More importantly for virus spread, asymptomatic virus reactivation and shedding occurs, and observations in seropositive persons have detected virus on approximately 3 percent of days studied. [1]The risks for HSV-2 seropositivity include female gender, age at first sexual intercourse, years of sexual activity, ethnic background (African American and Hispanic more so than white or Asian), drug use, and lower socioeconomic status. HSV-1 is now the cause of approximately half of all new cases of herpes genitalis in the United States[2]

Clinical Disease with HSV-1 and HSV-2

HSV-1 Disease

Primary HSV-1 infection most often presents as herpes gingivostomatitis in youngsters between the ages of 6 months and 5 years or as herpes pharyngitis in adolescents and young adults.[3]In children, this is a serious disease with high fever, listlessness, sore throat, and lymphadenopathy. In young adults, the disease presents as severe sore throat and tonsillitis. Recurrence of HSV-1 is called herpes labialis (frequently called cold sores or fever blisters) and presents with a prodromal tingling or burning followed within 6 to 24 hours by a cluster of vesicles or red papules at the vermilion border of the lips or adjacent skin on the face. Lesions evolve rapidly to a crusted ulcer in 2 days and heal in 6 to 10 days.

HSV-2 Disease

For HSV-2, the incubation period after sexual contact can range from 3 to 14 days but usually appears as vesicular lesions and denuded areas of genital mucous membranes within 1 week. Disease is more severe in women than in men, and symptoms include local pain, burning, tenderness of the involved areas, urethritis, constitutional symptoms of fever, headache, and malaise, and even meningeal symptoms. On moist areas, the initial vesicle ruptures quickly and a yellow-gray denuded ulcer surrounded by a red rim is seen; on dry skin, the vesicles progress to pustules and then dry and crust during a period of several days. The symptoms peak after 3 to 4 days, and viral shedding lasts for 12 to 14 days. Pain and local symptoms remit after 2 weeks, and complete healing occurs by 4 weeks. Recurrence of HSV-2 infection can appear as asymptomatic infection or as a painful cluster of vesicles in a localized area innervated by the pudendal nerves. The clinical syndrome after HSV-1 herpes genitalis is similar to that of HSV-2 but with less recurrence.

OTHER MANIFESTATIONS OF HSV-1 OR HSV-2 DISEASES

HSV-1 can spread to other sites of the body or can produce immune-mediated syndromes, which are described here.

Herpes Simplex Virus Keratitis and Other Ocular Disease

HSV-1 can be autoinoculated to the cornea during primary or recurrent infection. Lesions can be recurrent and result in scarring of the cornea. Stromal keratitis and iritis can occur after HSV infection.

Herpes Simplex Virus Encephalitis and Meningitis

HSV-1 encephalitis is the leading cause of sporadic acute necrotizing encephalitis in the United States; there are approximately 1,000 cases per year. This can occur either as a primary infection or as

recurrent infection.[4]Primary HSV-2 infection is often associated with cerebrospinal pleocytosis and symptomatic meningitis.[5]

Herpes Whitlow and Herpes Gladiatorum (Scrumpox)

HSV-1 and HSV-2 can infect remote or adjacent cutaneous sites after direct contact. Medical personnel and patients with oral or genital infection can autoinoculate by touching infected areas during herpes labialis or herpes genitalis. The infected paronychia is called herpetic whitlow. When infection occurs on the back, following contact with infected saliva during such interactions as wrestling or rugby, the condition is called herpes gladiatorum or "scrumpox."

Esophagitis, Hepatitis, and Enteritis

In the immunocompromised host, HSV-1 reactivation occurs in as many as 70 percent of patients, depending on the degree of immunosuppression. Oral infection can spread to the esophagus, small bowel, and liver. Perianal infection can spread to adjacent skin on the buttocks, producing painful skin ulcers.

Neonatal Herpes

Neonatal HSV infection occurs in 1 in 3,000 to 5,000 live births in the United States, with two-thirds of cases due to HSV-2 and one-third due to HSV-1.[6,7]The risk of infection is higher after primary maternal infection but can occur after recurrent herpes genitalis. Disease is usually of three types: disseminated infection involving multiple organs; portal-of-entry infection involving the skin, eyes, and mouth; and encephalitis with or without infection of skin, eyes, or mouth.

Eczema Herpeticum

Disorders of the skin, such as eczema, pemphigus, burns, or other dermatoses, can be infected with HSV and lead to widely disseminated and life-threatening infection. The generalized vesicular rash in this situation has been called Kaposi's varicelliform eruption. In burn units, this is a particular problem because HSV-1 reactivation can occur during stress, and autoinoculations of skin lesions can occur.[8]

Diagnosis of HSV-1 and HSV-2

Although viral culture has been a frequently used and reliable method of virus diagnosis, the most rapid method is indirect immunofluorescent staining of a lesion (swabbed specimen) examined on a slide.[4]This does not distinguish between HSV-1 and HSV-2, but type-specific antibody assays are commercially available. Polymerase chain reaction (PCR) assay can be effective at detecting HSV infection in body fluids or biopsy material.[4,9]

Treatment and Prevention of HSV-1 and HSV-2 Infection

HSV-1 and HSV-2 can be treated or prevented using antiviral agents. In addition to antiviral prophylaxis, the use of sunscreen for prevention of herpes labialis and condoms for preventing genital contact with viruses is recommended. Used daily, valacyclovir and acyclovir are highly effective in suppressing recurrences of genital herpes.[10,11]

VARICELLA-ZOSTER VIRUS

Nature of Varicella-Zoster Virus

VZV is the third of the alpha-herpesviruses; it can grow relatively rapidly with lytic infection but cannot maintain prolonged infection in tissue culture. The virus is distinct from HSV in both genetic sequence and clinical syndromes. The viruses of chicken pox and herpes zoster have been shown to be identical by physical and chemical analyses.

Epidemiology of Varicella-Zoster Virus Infection

VZV has no animal reservoir and spreads only from humans to humans. The primary infection with VZV causes a disseminated infection called chicken pox. Prior to the availability of the VZV vaccine, approximately 3.7 million cases of chicken pox occurred each year in the United States, 83 percent in children younger than 9 years.[12]Infection spreads via airborne mechanisms, with an infection rate of more than 90 percent in households with susceptible children. VZV infection occurred in as much as 95 percent of the population and was one of the most common infections of mankind. Immunity would quickly occur in an isolated population, so chicken pox spread from older immune generations to susceptible children by exposure to herpes zoster, the reactivation form of the viral life cycle. When a case of herpes zoster is the source of contact for a new case of chicken pox, it is likely that the virus spreads by direct contact with skin or skin squames. In households with a zoster exposure, the susceptible children have an infection rate of 25 percent.[13]There are approximately 1,000,000 cases of herpes zoster in the United States per year,[14]with the incidence constant for each age group through midadulthood. Herpes zoster incidence increases with increasing age, especially after age 50, is more common among immunocompromised persons.[15]

Clinical Aspects of Varicella-Zoster Virus Infection

Chicken Pox

In healthy children, VZV infection manifests as a vesicular rash often associated with prodromal malaise, pharyngitis, rhinitis, and abdominal pain. The rash appears 15 days after VZV exposure, with a range of 10 to 21 days. The vesicular eruption on skin emerges in successive crops during the first 3 to 4 days of illness, usually with an accompanying rash or spots on the mucous membranes. The skin vesicles begin on the head and quickly progress to the trunk, arms, and finally the legs (this may be termed a descending appearance), with rapid development of inflammatory changes and crusting in successive crops. A pathognomonic appearance is all stages of the rash, macules, vesicles, papules, and crusts, seen in the same region of the skin. The severity of disease is linked to the extent that the infection invades the mucosal surfaces of respiratory, alimentary, and genitourinary systems. The patient with chicken pox can have severe laryngitis, laryngotracheobronchitis, vaginitis, urethritis, pancreatitis, and enteritis. The immunocompromised host also may have severe abdominal pain or back pain, a hallmark of such progressive VZV infection.[16]

Herpes Zoster

Herpes zoster (also called "shingles" or "zona") occurs when VZV infection reactivates in cranial or spinal nerve ganglia, spreads to the cutaneous nerves, and infects the skin in the exact distribution of the nerve.[17]The most common area of involvement is the trunk, presumably because this is the area of greatest primary VZV infection, followed by cranial dermatomes, and then by cervical and lumbar dermatomes. Zoster is a syndrome of pain and vesicular eruption in a unilateral cutaneous distribution. If pain alone is present, without rash, the syndrome is called zoster sine herpete. The pain of herpes zoster that persists after the healing of skin lesions is termed postherpetic neuralgia and can last for

months. Virus reactivation in the spinal or cranial nerve ganglia, with the resultant intense inflammation and hemorrhagic necrosis of nerve cells, can result in nerve dysfunction manifested clinically by meningitis and myelitis, with or without paresis at sites of involved nerves. In addition, intense inflammation of the cutaneous site of infection results in scarring of the involved epidermis. This is of particular concern when the cornea or other ophthalmic structures are involved.

Diagnosis of Varicella-Zoster Virus Infection

The history and physical examination remain the primary methods for diagnosing chicken pox and shingles. In chicken pox, lesions are seen in all stages of development, including macules, vesicles, pustules, and crusted lesions, often with a history of recent exposure to a VZV infection. In certain individuals, especially those at high risk for complications of VZV infection, specific diagnosis can be pursued by laboratory methods. The most rapid and accurate method is the direct immunofluorescent stain of a skin scraping for VZV antigen using a commercially available kit. Conventional methods of culture of VZV or serology for VZV antibody also can be used to confirm the diagnosis, but these are rarely necessary in routine clinical practice.

Treatment and Prevention of Varicella-Zoster Virus Infection

Chicken pox and herpes zoster can be treated using antiviral agents. Because chicken pox is rarely seen in the vaccine era, it is important to be aware of management options necessary to minimize complications. Skin and subcutaneous infections are the leading bacterial cause of morbidity in patients with chicken pox, and attention to skin hygiene and early treatment of bacterial infections is important. Antiviral medication is not recommended in the otherwise healthy child but should be used in children with medical problems and in adults in whom there could be a predisposition to disseminated VZV infection.[18]

For the management of herpes zoster, the major concern should be for the control of pain and the prevention of inflammation that could alter organ function, for example, eyesight. Antiviral treatment has been shown to be effective using acyclovir, valacyclovir, famciclovir, and brivudine. The reader is referred to specialized text for the management of pain in these patients.[19]

The most important method for preventing chicken pox is use of the VZV vaccine. This vaccine is recommended for all healthy children and is also recommended for eligible healthcare personnel and day care workers, college students, prisoners, military recruits, nonpregnant women of child-bearing age, and international travelers who have not previously had VZV infection as indicated by negative antibody assay. For persons older than 60 years, there is a vaccine for prevention of herpes zoster.[17,20]

Varicella vaccine is recommended for postexposure administration for unvaccinated healthy people aged 12 months and older who are without other evidence of immunity to prevent or modify the disease. The vaccine should be administered as soon as possible within 5 days after exposure to rash, if there are no contraindications to use. The varicella-zoster immune globulin (VZIG) product used in the United States is currently available under an investigational new drug protocol. VZIG provides maximum benefit when administered as soon as possible after exposure but may be effective if administered as late as 10 days after exposure. If VZIG is not available, the U.S. Centers for Disease Control and Prevention (CDC) recommends that administration of intravenous immune globulin be considered as an alternative (also within 10 days of exposure).[21]

Although there are limited published data on the benefit of acyclovir as postexposure prophylaxis, if VZIG is not available some experts recommend prophylaxis with acyclovir beginning 7 to 10 days after

exposure for people without evidence of immunity and with contraindications for varicella vaccination.

The use of acyclovir and valacyclovir after organ transplantation lessens the incidence of VZV infection.[22,23,24,25] In addition, acyclovir can also be used to supplement VZIG to prevent chicken pox in high-risk newborns and children.[26,27]

CYTOMEGALOVIRUS

Nature of Human Cytomegalovirus

Human CMV is a beta-herpesvirus and is one of the most ubiquitous of the herpesviruses. Its growth in tissue culture is lytic but slower than the alpha-herpesviruses, and it was named for the cytopathic effect produced after infection. CMV is the largest of the human herpesviruses in size of genome, with approximately 240 kilobase pairs of DNA encoding nearly 200 proteins.[28] There are many strains of CMV, which probably accounts for the ability to be reinfected with multiple CMV infections. PCR assays that amplify the hypervariable regions encoding two surface glycoproteins, gB and gH, have been used to differentiate CMV strains by group.[29]

Epidemiology of Human Cytomegalovirus

With more than 60 percent of CMV-seropositive pregnant women excreting CMV in cervical sites and in breast milk, this virus is one of the first infections encountered by the newborn.[30] In addition, 1 percent of mothers who are seropositive at preconception transmit the virus to their child in utero.[31] If not infected during the neonatal period, the young child may receive additional exposure in day care centers, which have a 50 to 60 percent CMV excretion rate. Once infected, the child will excrete virus in saliva and urine for many months. Thus, CMV is spread by contact with infected persons in childhood. After puberty, sexual transmission of the virus occurs in 1 to 2 percent of the adult population seroconverts per year. CMV is also transmitted in blood products and organs.[32]

Clinical Syndromes of Cytomegalovirus Infection

Congenital Infection

Cytomegalic inclusion disease is the most severe manifestation of congenital CMV infection and results from intrauterine infection in the first and second trimesters of pregnancy, occurring in 3,000 to 4,000 infants annually in the United States.[31] Hepatosplenomegaly is universal, and cutaneous hematopoietic elements create a "blueberry muffin" appearance to the skin. Infection of the brain occurs, with resultant microcephaly, intrauterine growth retardation, and postnatal mental and motor retardation. CMV is the leading infectious cause of mental retardation in the United States.

Subclinical congenital CMV infection occurs when congenital infection is in the late second and third trimester and presents late with sensorineural hearing loss, school failure, and motor impairment. Preterm infants can be infected with CMV through blood transfusions, and this can result in pallor and hypotension ("gray baby syndrome") and respiratory distress.

Cytomegalovirus Mononucleosis and Hepatitis

The vast majority of primary CMV infections in healthy persons are asymptomatic, but infection can be associated with nonspecific symptoms of fever, malaise, mononucleosis with or without hepatitis,

leukopenia, and atypical lymphocytosis, particularly in otherwise healthy young adults. This heterophile-negative mononucleosis can occur after heart-lung bypass, where it is termed "postperfusion syndrome," and in patients in intensive care and burn units.[33,34]Chronic fatigue syndrome has been anecdotally associated with CMV infection, but it is not clear whether this is due to the CMV itself or whether CMV is associated because of its ubiquitous nature.

Transplantation and AIDS-related Cytomegalovirus Infection

Overview

Formerly, human CMV was considered a pathogen only for the fetus. But it is recognized to be a more serious pathogen in the organ transplant recipient, in whom it produces a range of syndromes from fever, leukopenia, and thrombocytopenia to more serious organ-specific dysfunction, with or without bacterial and fungal superinfections. It was first noted to produce significant disease in the SOT population. During the first decade of marrow transplantation, CMV was the leading infectious cause of death.[35]In addition, in the pre-antiretroviral therapy era of AIDS, CMV was a significant cause of morbidity and mortality. It is observed that there is increased disease and mortality in SOT of CMV seropositive donors to seronegative organ recipients. However, in HSCT, when the transplant donor is CMV seropositive and the recipient seronegative, protection from CMV infection is conveyed through the transfer of memory T cells.[36]A significant reduction in CMV disease has occurred in patients with AIDS, who receive human immunodeficiency virus (HIV) treatment and have at least partial recovery of CD4 lymphocytes to more than 200 cells/μL. This attests to the importance of immunologic control of CMV in disease pathogenesis. Thus, among the risk factors for CMV disease, immunosuppression or immunodeficiency is of primary importance. The absence of CMV-specific, CD4-positive, T-cell function is a marker for risk of CMV disease.[37,38]In addition, patients with detectable cytotoxic T-lymphocyte (CTL) activity targeted to CMV have much less disease than do those without CTL.[39,40]

Interstitial Pneumonia

Cytomegalovirus-interstitial pneumonia (CMV-IP) presents with dyspnea (air hunger) and oxygen desaturation in blood and progresses to respiratory failure.[35]This is a particular problem in organ transplantation, and in the absence of preemptive antiviral therapy, the usual onset of CMV-IP is during the 2 months after the transplantation. With preemptive therapy, the onset of disease is 150 to 180 days after transplant. Treatment requires respiratory support and control of the virus infection. The use of immunosuppressive drugs should be decreased as much as possible. Antiviral therapy uses either ganciclovir or foscarnet, with the addition of intravenous immunoglobulin. Although this use of intravenous immunoglobulin has not been established with controlled trials, it has become conventional therapy in the marrow transplant patient on the basis of case reports.[41]

Cytomegalovirus Enteritis

CMV infection can involve any location in the gastrointestinal system, from esophagus to rectum, with or without hepatitis. The classical presentation is with fever, loss of appetite, and abdominal pain. In severe infection, diarrhea and abdominal bleeding, with or without perforation of the bowel, can occur.

Cytomegalovirus Retinitis

In the pre-antiretroviral therapy era in AIDS, the most frequently seen form of CMV disease was retinitis. With improved treatment of AIDS, the incidence of retinitis has decreased significantly. [42]Currently, CMV retinitis is seen primarily in patients with AIDS and antiretroviral failure and in SOT recipients on long-term immunosuppression.[43]The disease presents with variable degrees of monocular visual impairment and funduscopic findings of yellow-white exudates with or without hemorrhage. In advanced disease, both eyes become involved, and there is eventual retinal detachment and blindness. In some newly treated patients with AIDS who have recovering CD4+ counts, there is a syndrome of vitreous inflammation and macular edema, which is called "immune reconstitution disorder" due to a restored immune response to occult CMV infection of the eye.[44]

Diagnosis of Cytomegalovirus Infection

Active infection with CMV can be diagnosed by PCR or viral culture of CMV from urine, saliva, throat swab specimens, or other body tissues. Serologic tests that detect CMV antibodies (IgM and IgG antibody to CMV) are widely available from commercial laboratories. Tissue culture isolation of CMV is rarely used, but methods for detection of CMV by histology or of CMV antigens by immunohistochemistry are frequently used methods for diagnosis. The enzyme-linked immunosorbent assay (ELISA) is the most commonly available serologic test for measuring antibody to CMV. Various fluorescence assays and indirect hemagglutination and latex agglutination tests are also available.[45]

There are two general categories of CMV diagnostic assays, those that depend on virus infection in tissue culture for a positive end point and those that require molecular methods for detection of virus protein, RNA, or DNA. Detection of CMV pp65 in granulocytic nuclei, utilizing monoclonal antibody staining of peripheral blood leukocytes, can be used to document early CMV dissemination in immunocompromised patients. [46]This CMV antigenemia assay correlates with CMV blood infection, and the onset of antigenemia precedes the detection of "infectious" CMV using the culture-based assays. [47] Thus, the antigenemia assay is a surrogate marker for CMV blood infection and, as such, has become a valuable tool for determining the preemptive use of antiviral agents.[48]

Among the molecular methods of CMV detection are the PCR assay, the DNA hybrid capture assay, and the nucleic acid sequence-based amplification. [49]The PCR assay is a versatile method for diagnosing CMV and can be used for quantitative characterization of CMV infection. PCR assay improves the early detection and treatment of CMV infection after transplantation.[50]Quantitative PCR is particularly useful for monitoring the response to treatment.[51]

The hybrid capture systems use a synthetic strand of RNA to "find" a strand of homologous DNA from a clinical specimen. This "hybrid" RNA/DNA is captured in a tube coated with antibody to RNA/DNA complexes and then detected using an antibody-based assay.[49]The specificity of the CMV hybrid capture assay is similar to that of the antigenemia assay[52]and compares well with PCR-based methods in the care of transplant patients.[53]The nucleic acid sequence-based amplification assay (NASBA) detects CMV using an RNA amplification technique in which a CMV-specific RNA molecule can be made into DNA and then serve as a template for amplification of RNA copies, which are then detected.[49]A potential advantage of the RNA amplification system is that a positive result indicates the presence of actively replicating virus. The NASBA compares well with PCR and blood culture when used to manage antiviral

therapy in transplant patients.[54]The ultimate choice of assay to use should be based on clinical need, and the most important needs are detection of CMV infection early enough to prevent disease and confirmation of treatment response or failure. It is clear that the PCR, hybrid capture, and NASBA assays report the earliest detection times of CMV reactivation. However, the antigenemia assay has the advantage of low-technology requirements and ease of performance. But the choice of assay must be made based on the resources at each medical center and the type of patients treated.[49]

Treatment of Cytomegalovirus Infection

Antiviral Agents for Cytomegalovirus Prevention

Ganciclovir, foscarnet, and cidofovir are antiviral drugs approved for the treatment of CMV infection. Valganciclovir is an oral agent with high bioavailability and is the drug of choice for prevention of CMV in SOT patients. Foscarnet is especially useful when there is concern about the marrow toxicity of ganciclovir. Because foscarnet is associated with nephrotoxicity, hypocalcemia, and hypophosphatemia, attention must be given to adequate hydration and electrolyte balance. Foscarnet is usually administered intravenously with concomitant administration of saline. Attention must be given to Mg++ and Ca++ levels, and this can be supplemented with an infusion of magnesium sulfate and potassium phosphate with calcium supplementation if hypocalcemia occurs.

Risk-Adapted Prophylactic Antiviral Management

There are two methods of CMV prevention: preemptive use of antiviral agent and risk-adapted prophylaxis. The preemptive strategy for prevention of CMV disease aims at early treatment of reactivated infection prior to the onset of disease. This method relies critically on an efficient method for surveillance and reporting of CMV reactivation following HSCT. CMV infection in blood or in the lungs of patients with asymptomatic disease is the significant risk factor for subsequent disease. In the preemptive strategy, ganciclovir is given to asymptomatic transplant recipients at the time of laboratory-positive active CMV infection of blood.[55,56]The goal of preemptive ganciclovir use is to limit exposure of this marrow-toxic agent to persons who have demonstrated reactivation of CMV infection.

Control of Iatrogenic Cytomegalovirus Transmission

The risk of CMV infection in the low-birth-weight neonate and in the CMV-seronegative transplant recipient, for whom the donor is also CMV seronegative, is determined by exposure to blood product support. When blood components are filtered, nearly all primary CMV infection can be prevented, and no preventive antiviral treatment is necessary in this population.[57,58,59]

EPSTEIN-BARR VIRUS

Nature of the Epstein-Barr Virus

EBV is a gamma-herpesvirus, meaning that the virus can cause both lytic and nonlytic infection and, more importantly, can maintain itself in long-term chronic active infection. Its ability to induce cell replication contributes to its oncogenicity. The EBV genome contains 172 kilobase pairs of double-stranded DNA. There are two types of EBV, type 1 and type 2 (sometimes called type A and type B), which differ primarily in the nuclear antigens expressed during latency. In Western countries, type 1 predominates, but in Africa the types are equally prevalent.[60]The biologic aspects of EBV replication, which contribute to lymphoproliferation and malignancy, are described later in this chapter.

Epidemiology of Epstein-Barr Virus

The EBV virus grows in the epithelium of the oropharynx, and shedding into saliva explains the transmission of infection from such activities as kissing and sharing glassware. Among lower socioeconomic groups, EBV spreads in childhood; in industrialized societies, infection occurs in adolescents and young adults. The virus spreads systemically and infects B lymphocytes, which become a primary site of infection and in which the virus persists indefinitely.[61]Transfusion of blood and tissue transplantation can spread EBV to susceptible recipients.[62,63]

Clinical Diseases of Epstein-Barr Virus

EBV is most important as the cause of infectious mononucleosis and is associated with neoplastic diseases such as nasopharyngeal carcinoma,[64]Burkitt lymphoma,[65,66]non-Hodgkin lymphoma in AIDS,[67,68]and Hodgkin disease.[68]The pathogenesis of EBV-associated disease is in part directly related to the immune status of the infected person. A healthy immune response to initial infection induces a T-cell response that produces an atypical lymphocytosis and the enlarged lymph nodes (colloquially called "glands") seen in mononucleosis (previously called "glandular fever"). Any state of chronic immunosuppression, such as occurs after SOT, or inborn immunodeficiency, such as the X-linked lymphoproliferative syndrome, can result in prolonged EBV infection, providing the molecular environment for potential neoplastic changes in lymphoid cells. Posttransplant lymphoproliferative disease (PTLD) is defined as a spectrum of abnormal proliferation of lymphoid cells in response to EBV with or without malignant neoplastic change. The pathogenesis of PTLD is based on the interaction between EBV and B cells and the treatment-related modification of immune factors necessary to control this interaction.[69]

Infectious Mononucleosis

Infectious mononucleosis (IM) is a syndrome characterized by sore throat, exudative pharyngitis, fever, lymphadenopathy with or without malaise, anorexia, headache, myalgia, and hepatosplenomegaly. In the immunosuppressed patient, unlike the immunologically healthy person in whom the T-lymphocyte response contributes the "mononuclear" element to the hematologic findings, there is not a true hematologic mononucleosis. Similarly, the serologic findings important in the diagnosis of EBV infection are not reliable in the immunosuppressed population, and a direct EBV DNA detection method (PCR assay) should be used for assessing infection.[70,71,72]

Posttransplant Lymphoproliferative Disease

The same nonspecific signs of fever and malaise can occur at the start of PTLD, and the syndrome eventually presents as a focal or multifocal occurrence of lymphoid proliferation.[73]Focal proliferations of lymphoid cells can occur nearly anywhere, but the most common areas involved are the central nervous system, the gastrointestinal tract, and the lymphoid system.[74,75,76]Aggressive immunoblastic lymphoma can be seen early after transplantation.[77](For a complete review of this disorder, see the online resource of Transplantation Pathology Internet Services.)

Hairy Leukoplakia

Although more rare in the transplant patient than in the patient with untreated AIDS, chronic EBV infection can cause hairy leukoplakia. Oral hairy leukoplakia presents as a white lesion on the tongue or

oral mucosa due to epithelial hyperplasia. When EBV is present, it can be detected in the epithelial cells in these lesions, and it is known to replicate using viral polymerase to produce high amounts of infectious virus.[78]Replication by viral polymerase distinguishes the lytic form of infection from a latent form, which replicates using cellular enzymes. The lytic form is susceptible to antiviral agents.

Epstein-Barr Virus-induced Neoplasms

EBV has been associated with several neoplasms; the most common are nasopharyngeal carcinoma and lymphoma. The EBV-induced proliferation of cells leading to malignancy occurs in two stages: the first is the actual induction of proliferation, and the second stage is the development of a fixed genetic change by means of chromosomal or other mutational alteration.[66,69]After transplantation surgery, non-Hodgkin lymphomas are associated with EBV in 90 percent of instances of this complication.[68]Prior to the availability of rituximab, the association of EBV with non-Hodgkin lymphoma occurred in more than 70 percent of cases associated with prior PTLD.[79,80]In addition to B-cell neoplasms, EBV has been found in association with approximately 25 percent of T-cell lymphomas occurring in transplant recipients.[81]

Diagnosis of Epstein-Barr Virus

IM is characterized by a relative and absolute lymphocytosis, with atypical lymphocytes often more than 10 percent of the total white blood cell count. A heterophile antibody response is made following acute infection, and the diagnosis is usually confirmed when patients present with the triad of fever and pharyngitis, atypical lymphocytosis, and positive heterophile antibody. EBV infection can be confirmed with a panel of antibody tests to the EBV early and late proteins. Chronic active EBV is a poorly understood syndrome consisting of persistent mononucleosis symptoms, an unusual pattern of EBV antibodies, and increased EBV genomes in tissues. In the management of immunosuppressed patients, a quantitative PCR assay can be used to diagnose and assess reactivation of EBV infection.[82,83]

Treatment of Epstein-Barr Virus Infection

General Approach

EBV is inhibited in vitro by several antiviral agents, including acyclovir, ganciclovir, foscarnet, penciclovir, and interferon. However, only oral hairy leukoplakia responds effectively to acyclovir. There is little clinical benefit from antiviral agents during IM, chronic mononucleosis,[84]and even fulminant infection associated with X-linked immunoproliferative syndrome.[85]These agents inhibit only the replication of linear EBV DNA that occurs during lytic infection when EBV-encoded DNA polymerase is active. Such is the case with acyclovir in hairy leukoplakia. But these agents have no influence on the episomal form of virus found in latently infected cells that replicate using cellular enzymes. This explains why EBV-seropositive persons treated with acyclovir continue to have cultivatable EBV in circulating lymphocytes.[86]Nevertheless, acyclovir and ganciclovir have been used in PTLD with occasional reports of success.[87] Ganciclovir is more active than acyclovir against EBV in vitro and can effectively reduce the nasopharyngeal excretion of EBV after transplantation.[88]

Management of Epstein-Barr Virus in Immunosuppressed Patients

PTLD is a life-threatening complication of all transplantation groups. It is associated with a mortality of more than 50 percent if untreated. For PTLD, reduction in immunosuppression is the first aspect of patient care. Local control of disease is important, particularly if associated with gastrointestinal bleeding, so surgical intervention should be considered based on the disease presentation. Monitoring of EBV PCR in at-risk patients and preemptive treatment has been shown to be useful in the prevention of PTLD.[86,89] Treatment consists of administration of a monoclonal antibody, called rituximab, with specificity for B-cell surface proteins that has been approved for the treatment of B-cell lymphomas.[90] Antiviral therapy is helpful only if the virus remains in the early lytic phase of infection, and there are anecdotal experiences with improvement in PTLD. In addition, an important interventional treatment-influencing outcome of PTLD is adoptive humoral and cellular immunotherapy.[91,92]

HUMAN HERPESVIRUS-6 AND HUMAN HERPESVIRUS-7

Nature of HHV-6 and HHV-7

HHV-6 and HHV-7 are both classified in the genus *Roseolovirus*, both are beta-herpesviruses, and both are distinct viruses based on their genetic composition. These two viruses are considered together here because of the similarity of disease presentation and epidemiology. HHV-6 was first isolated from patients with B-cell lymphoproliferative diseases, but the virus replicates primarily in T lymphocytes with a preference for CD4 cells. HHV-6 is related genetically and antigenically to CMV with two serologic strains: HHV-6A and HHV-6B. HHV-6A is associated with infection in immunosuppressed adults, especially patients with AIDS and transplant recipients. HHV-6B is associated with infection in infancy, especially febrile syndromes, febrile convulsions, and rash.

HHV-7 is a T-lymphotropic virus, and infection can occur in persons with high HHV-6 antibody, indicating that the two viruses do not result in cross-protection. Less is known about HHV-7, and except for anecdotal associations with syndromes similar to HHV-6 and an unconfirmed association with pityriasis rosea, there is no clear understanding of HHV-7-induced disease.

Epidemiology of HHV-6 and HHV-7

HHV-6 is present in vaginal secretions and saliva; seroconversion occurs in most infants between 6 months and 2 years of age. The peak infection begins late in the first year as the maternal antibody declines, and by 3 years of age approximately 95 percent of children have been infected with this virus. This widespread occurrence of infection early in life suggests that the virus has an efficient mechanism for spread. HHV-6 is present in saliva and can be detected in 85 percent of healthy adults.[93] Thus, it appears that virus is spread by contact with oral secretions. Maternal and child isolates are identical, suggesting the source of virus is within the household. HHV-7 infection occurs slightly later in infancy and early childhood and is also present in oral secretions, suggesting a route of spread that is similar to that of HHV-6.

Clinical Features of Infection

Primary Infection

HHV-6B is associated with roseola (also called "infantum subitum" or "sixth disease") and febrile seizures in infants. Primary HHV-6 infection usually occurs before 2 years of age, producing 3 to 4 days of high fever, followed by sudden loss of fever and the appearance of generalized macular-erythematous rash, thus the name "exanthem subitum." The virus appears to have an affinity for the

CNS and has been associated with up to a third of febrile convulsions in infancy[94] and with encephalitis.[95] In adults, there have been case reports of mononucleosis with or without rash and of demyelinating CNS disease associated with HHV-6. As noted, the clinical spectrum of HHV-7 is not known, but it has been associated with roseola-like syndrome in children.

Reactivation Disease

The seroprevalence for HHV-6 and HHV-7 after childhood approaches 100 percent, so virtually all organ donors and recipients can be assumed to be HHV-6 and HHV-7 antibody positive. Following bone marrow transplantation, HHV-6 reactivates in 36 to 46 percent of recipients, and this occurs during the first 1 to 2 months after transplant.[96,97,98,99] The generally high seroprevalence of HHV-6 has made clear separation of virus causality difficult in the HSCT population, in which several herpesviruses, especially CMV and EBV, can reactivate at the same time. A retrospective analysis of HHV-6 infection in children undergoing allogeneic HSCT with and without ganciclovir prophylaxis suggests that ganciclovir prevented HHV-6 reactivation, and in those with reactivation, the clinical syndromes included skin rash, interstitial pneumonitis, persistent thrombocytopenia, enterocolitis, and thrombotic microangiopathy. In addition, cases of graft failure have been noted in association with rising HHV-6 DNA levels.[100] Analysis of clinical syndromes associated with high levels of HHV-6 DNA in allogeneic recipients of HSCT showed encephalitis and poor platelet engraftment.[98]

Because of the preference of HHV-6 for neurologic tissue, an evaluation of encephalitis after allogeneic bone marrow transplantation was made, and results suggested a correlation with HHV-6 infection.[1] HHV-6 DNA has been observed in cerebrospinal fluid specimens from as many as 25 percent of marrow transplant patients with CNS symptoms.[101,102] HHV-6 encephalitis is associated with seizures and abnormal electroencephalogram findings but not with cerebrospinal fluid pleocytosis or pathognomonic findings from imaging studies. Microangiopathic syndromes have been associated with HHV-6 after autologous HSCT.[103] In addition, HHV-6 has long been thought to be a cause of interstitial pneumonitis, and it appears to be a minor cause of the disease in this population, with CMV being the major cause. Of note, mixed infection with HHV-6A and HHV-6B has been found in autopsy studies, suggesting that multiple infections with strains of HHV-6 occur in the HSCT population.

Laboratory Diagnosis

The diagnosis of HHV-6 infection can be made by virus isolation from blood, PCR assay in clinical specimens, and serologic tests for antibody. Acute and convalescent antibody assays, using an ELISA or indirect immunofluorescent-antibody (IFA) method, can be used for diagnosis of primary infection. PCR is most useful when evaluating tissue specimens related to organ-specific syndromes, but because HHV-6 DNA could be derived from cells infected at remote times, an RNA-based assay should be used to confirm active infection.[104]

Treatment of HHV-6

HHV-6 is susceptible to ganciclovir and foscarnet and only relatively susceptible to acyclovir. Foscarnet or ganciclovir are recommended as first-line agents for treatment of this infection.

HUMAN HERPESVIRUS TYPE 8

Nature of HHV-8

Human herpesvirus type 8 (also called KSHV) is a gamma-herpesvirus that was first discovered in KS of patients with AIDS. As a gamma-herpesvirus, HHV-8 induces cell proliferation and has been linked to three hematopoietic neoplasms: KS, multicentric Castleman disease, and primary effusion lymphoma (PEL). [5]KSHV is classified as a gamma-2 herpesvirus, or rhadinovirus, and it differs from EBV in the manner by which it alters cell cycle. KSHV incorporates certain cellular gene homologs, thereby modifying the cellular control of proliferation and survival.

Epidemiology of HHV-8

The epidemiology of KSHV is complex, with global distribution of virus but with low endemicity, except in pockets of high prevalence in Africa, in certain South American tribes, and in males who have sex with males (MSM). The virus is present in saliva and, based on intrafamily spread of infection in Africa, it is likely that the virus spreads via contact with oral secretions. Among MSM populations, the spread of KSHV was initially thought to be via semen, but the titers of virus are highest in saliva, and it is now thought that oral contact is the main route of spread, although oral-genital routes cannot be excluded. It is not known why, if the virus is present in saliva in high titers, the seroprevalence of KSHV is so low in most populations. KSHV could be a newly emergent infection that is only now spreading globally. In developed countries, the virus has become a problem in medically challenged patients with spread via blood and body organs. Thus, KSHV infection is an increasing problem in transplant populations.

In the transplant setting, treatment-related KS is seen primarily in SOT and predominantly in renal allograft recipients with only rare occurrences in HSCT. In renal transplant recipients, the incidence of KS varies and can be as high as 23 percent in recipients with antibody to KSHV.[105,106]There is suggestive evidence that the virus infection is transferred from donor to recipient by the allograft. Detection of KSHV DNA in the donor organ or of antibody in the recipient has been found prior to the onset of KS, suggesting that the risk of infection could be defined with these tests. The occurrence of KS appears to be associated with the degree of immunosuppression, and the reports have indicated that use of mycophenolate mofetil after renal allografting has increased the incidence of KS.[107]

Disease Associated with Kaposi's Sarcoma-associated Herpesvirus

KS is a complex lesion with vascular, spindle-shaped cells derived from endothelium and inflammatory cells derived from monocytes and macrophages. PEL is a tumor of B lymphocytes that proliferates in body cavities such as the pleural space and peritoneum. The lymphocytes contain KSHV genomes in nearly all PEL tumors, and 70 percent also have latent EBV. Multicentric Castleman disease is a reactive proliferation of B lymphocytes, producing a plasmablastoid accumulation of cells in enlarged lymph nodes. The disease is not a malignancy per se but appears to be a reaction to the viral interleukin-6 (IL-6) and cellular IL-6 that is induced by the KSHV infection. Other syndromes associated with KSHV and seen in transplant patients are aplastic anemia, fever, cutaneous rash, hepatitis, lymphoid proliferation that mimics primary effusion lymphoma, and EBV-related PTLD.

Diagnosis of Kaposi's Sarcoma-associated Herpesvirus

Serologic assays for antibody to KSHV are generally research tools because of the various latent and lytic antigens used for the antibody detection. As with EBV, the antibody assays that are becoming useful clinically use protein antigens that represent either the latent or the lytic phase of infection. The diagnosis of KSHV is usually generated from a pathology specimen indicating one of the neoplasms known to be associated with this virus; PCR assays are available to confirm virus infection.

Treatment of Kaposi's Sarcoma-associated Herpesvirus

There is no antiviral treatment for KSHV. The treatment of neoplastic syndromes associated with KSHV in immunodeficient populations includes chemotherapy and radiotherapy. In populations that receive treatment-related immunosuppression (e.g., SOT patients), the recommendation is to reduce or withdraw immunosuppressive medication to permit the immune system to recover and suppress the KSHV.[108]

Conclusions

The Herpesviridae is a large family of viruses found among all vertebrates, with eight known to infect humans within three subfamilies: alpha-, beta-, and gamma-herpesviruses. Each of the eight has certain laboratory and clinical features in common. The viruses may present as a chronic intermittent infection fluctuating between low-level activity or "latency" and high-level replication or "reactivation." Infections vary from rashes to malignancies. The eight human strains were highlighted in this chapter, including methods for prevention and treatment.

Future Trends

VACCINES FOR HERPESVIRUSES

The only approved vaccine for a human herpesvirus is the VZV vaccine, but with several vaccines for animal herpesviruses, it is suggested that there eventually will be vaccines for other human herpesviruses. Among the most widely tested experimental vaccines are those for HSV and EBV.[109,110]

EBV vaccines have been used in the experimental treatment of EBV-associated Hodgkin disease and may yield a vaccine that is useful in the general public. A critical need identified by the National Institutes of Health in the United States is the development of vaccine to prevent the morbidity and expense associated with congenital CMV infection. At present, several vaccines are in trials, and it is likely that a CMV vaccine will be available in the near future.

UNDERSTANDING IMMUNITY TO THE HERPESVIRUSES

Recently reagents have become available for quantitation of virus-specific CD4- and CD8-positive T cells after natural infection and in immunosuppressed populations. These studies have demonstrated that for EBV and CMV, and likely for the other beta- and gamma-herpesviruses, there is a major commitment by the immune system to the control of these infections. It is not unusual to see 10 to 12 percent of total CD8 cells committed to a single peptide epitope of CMV or EBV, and because there are potentially hundreds of immunological targeted epitopes of these herpesviruses, it is possible that the majority of our T cells are directed toward these viruses. This burden of immune surveillance over time has even been suggested to result in eventual immune fatigue and lead to pathology in elderly persons.

With regard to HSCT populations, quantitative tests of cellular immunity have shown that donor immunity contributes substantially to the CMV-specific cellular immune status of the recipient. In the future, such quantitative immunologic assessment methods may prove useful for defining risks for other herpesviruses and for deciding which patients need antiviral therapy.

Cell-Based Gene Therapy for Herpesviruses

In EBV and in CMV, improved methods for scale-up of EBV-specific cytotoxic T lymphocytes (CTLs) from normal marrow donors have been developed. This type of approach illustrates the potential for cellular therapy to eliminate EBV complications after transplantation. Gene transfer approaches are also being

considered for prevention of PTLD by prophylactic infusion of EBV-specific CTLs.[111]The use of such immunotherapy is being studied for prevention of CMV disease in HSCT. The major complication of such treatment would be graft-versus-host disease, and other genetic manipulations have been suggested to protect the recipient from potential T-cell reactivity.[61]

International Perspective

The herpesviruses are global in the human population. Areas with endemic diseases that affect the immune systems, such as HIV causing AIDS, can have higher rates of infection in these populations.

Abstract

The human immunodeficiency virus and its resultant acquired immunodeficiency syndrome has transitioned from an acute to a chronic disease. Therefore, there are significant challenges to both care of the patient and care of the community through transmission prevention. For healthcare personnel, there is a need to understand the transmission, social, legal, and treatment issues. This chapter presents an overview of the background, transmission, prevention, and treatment of human immunodeficiency virus infection and acquired immunodeficiency syndrome, as well as information on legal and confidentiality issues relating to human immunodeficiency virus/acquired immunodeficiency syndrome.

Key Concepts

- Although studies show that human immunodeficiency virus may have jumped from chimpanzees to humans as far back as the 1800s, it was first recognized in man in the United States as recently as the late 1970s.
- Human immunodeficiency virus affects specific cells of the immune system called CD4 cells, or T cells, subsequently compromising the natural immune system's ability to fight off infection.
- Acquired immunodeficiency syndrome is the stage of human immunodeficiency virus when the immune system is so badly damaged that the person develops opportunistic infections and

cancers. Without treatment, people who develop acquired immunodeficiency syndrome typically survive about 3 years.

- Only certain body fluids (blood, semen ["cum"], preseminal fluid, rectal fluids, vaginal fluids, and breast milk) from a human immunodeficiency virus-infected person can transmit human immunodeficiency virus to another person.
- Three-fourths of all cases are sexually transmitted through having unprotected sex.
- Globally, more than 34 million people are living with human immunodeficiency virus.
- As newer human immunodeficiency virus diagnostic methods are developed, the ability to identify human immunodeficiency virus infection in the early stages of transmission also improves.
- Although there is no cure, treatment with antiretroviral medications has improved survival.
- The use of drug-resistant testing has become an important part of human immunodeficiency virus clinical care.
- Although historically vaccines have been the best weapon against the world's most deadly diseases, there is unfortunately no effective human immunodeficiency virus vaccine available.
- Key components of a human immunodeficiency virus prevention program center on the use of Standard Precautions in healthcare settings, risk reduction through behavioral modification programs, and medication adherence programs.

Background

The human immunodeficiency virus (HIV) originated in Africa. Retrospective studies of sera indicate that the virus was present in sub-Saharan Africa in the 1950s. All studies of sera collected during the 1960s in many parts of the world indicate a very low prevalence of HIV antibodies. The epidemic transmission of the virus began in the 1970s and early 1980s. A timeline of some of the most historically important aspects of this includes the following:

- 1959: First documented case of acquired immunodeficiency syndrome (AIDS) in the world. The patient was a sailor from England who died of *Pneumocystis carinii*pneumonia (PCP) and cytomegalovirus infection. (Note that this organism has been renamed *Pneumocystis jirovecii*.) Studies of stored tissue from the patient proved that the patient was infected with HIV.
- 1968: The first documented case of AIDS in the United States. Retrospective studies indicated the presence of HIV infection in a young patient who was found to have Kaposi's sarcoma at autopsy.
- 1981: Previously healthy homosexual men with biopsy-confirmed PCP and Kaposi's sarcoma were reported from California and New York. Common to these cases was an underlying severe cellular immunodeficiency marked by a dramatic reduction in CD4 lymphocytes. These were the first reported cases of AIDS, a disease that at that time was of unknown etiology.
- 1984: Recognition of the human immunodeficiency virus type 1 (HIV-1) as the etiologic agent of AIDS.

- 1985: A serologic test to detect HIV antibodies was developed. With implementation of the test in blood banks, the risk of acquiring HIV after a blood transfusion decreased significantly.
- 1986: A second type of HIV virus is identified in patients with AIDS from West Africa. HIV-2 produces the same clinical manifestations as HIV-1 but causes disease almost exclusively in Africa.
- 1987: The U.S. Food and Drug Administration (FDA) approved AZT (zidovudine), the first anti-HIV drug.
- 1995: A new class of very potent anti-HIV drugs, the protease inhibitors, is available for clinical use. After an initial hope that combination therapy using these potent new drugs may cure the infection, clinical studies indicate that eradication of HIV infection cannot be achieved with our current therapy.
- 2000: The United Nations estimated that as of December 2000, 58 million people had been infected with HIV.
- 2011: At the International AIDS Society's Conference on HIV Pathogenesis, Treatment, and Prevention, scientists announce that two studies have confirmed that individuals taking daily antiretroviral drugs experienced infection rates more than 60 percent lower than those on a placebo.[1]

Basic Principles

EPIDEMIOLOGY

A national surveillance system has been in place in the United States since the first reported cases in 1981. All 50 states require reporting of AIDS cases to the local health authorities, which then report to the Centers for Disease Control and Prevention (CDC). The first 100,000 cases of AIDS were reported to the CDC over an 8-year period. The second 100,000 cases were reported over a 2-year period. As of June 2011, approximately 1,148,200 cases of HIV have been reported to the CDC.[2]

Minorities are overrepresented in the U.S. AIDS epidemic, particularly African Americans (approximately 60 percent of cases) and Hispanic Americans (approximately 20 percent of cases). Male-to-male sexual contact is the most prevalent mode of transmission.[3]AIDS is the sixth leading cause of death among people 25 to 44 years of age in the United States, down from number one in 1995.[4]In the United States, 1,148,200 people are living with HIV, with an additional estimated 207,600 of those undiagnosed. There were about 47,500 new infections in the United States in 2010, with the number of new HIV infections highest among individuals 25 to 34 years of age (31 percent), followed by individuals 13 to 24 years of age (26 percent).[3]

The World Health Organization (WHO) estimated that 34 million people were living with HIV at the end of 2011.[5]The number of those newly infected has fallen, particularly in the Caribbean and sub-Saharan Africa. However, the number of newly infected persons in the Middle East and

North Africa has increased. The incidence of newly infected persons in the United States has remained stable.[5]

TRANSMISSION

The HIV virus is relatively fastidious and cannot survive for long periods outside the human body.[6]The virus can be transmitted as free virus in secretions or as cell-associated virus by transmission of live cells (e.g., blood products, breast milk, semen). Transmission requires parenteral, broken skin, or mucous membrane contact with contaminated blood or body fluids or both. Fluids such as saliva, tears, urine, and sweat should not be considered a transmission risk unless blood is present.[6]

The epidemic was first described in men having sex with men, but other risk groups were rapidly identified, including injection drug users (IDUs) and recipients of blood products.[7]Approximately 70 percent of U.S. cases are in those practicing male-to-male sex or in IDUs. Heterosexual transmission accounts for approximately 30 percent of U.S. HIV transmission.[8]Worldwide, however, most of the cases are heterosexually acquired. In the United States, females outnumber males in the heterosexual risk category. Part of the explanation for the growing number of females in the heterosexual risk category may be that male-to-female transmission is approximately twice as efficient as female-to-male transmission. HIV can also be transmitted from pregnant women to their unborn babies during the birthing process.

Fluids (blood, semen, vaginal secretions, and breast milk) from an HIV-infected person can transmit HIV. These fluids must come in contact with a mucous membrane or damaged tissue or be directly injected into the bloodstream (from a needle or syringe) for transmission to occur. In the United States, HIV is most commonly transmitted through sexual behaviors (anal or vaginal sex) or sharing needles with an infected person. It is less common for HIV to be transmitted through oral sex or for an HIV-infected woman to pass the virus to her baby before or during childbirth. It is also possible to acquire HIV through exposure to infected blood, transfusions of infected blood, blood products, or organ transplantation, though this risk is extremely remote due to rigorous testing of the U.S. blood supply and donated organs.[6]

The first test to detect antibodies to HIV was licensed in March 1985. Since that time, all blood and tissue donors have been tested. However, because screening tests measure antibodies to the virus, which may take up to 6 months after exposure to appear, the probablility of transmission via blood products, though extremely low, still exists. All blood donors are also questioned regarding behavioral risk factors for HIV and recent flulike symptoms. The risk for acquiring HIV infection through blood transfusion today is estimated conservatively to be one in 1.5 million, based on 2007–2008 data.[9]

PREVENTION

The most important step in prevention is education.[10]The public needs to be made aware of risk behaviors that transmit HIV. Furthermore, the HIV/AIDS Strategy for the United States, supported by CDC, recommends using a combination of scientifically proven, cost-effective, and

scalable interventions and prevention strategies directed toward the most vulnerable populations in the United States who are most affected by, or at greatest risk for, HIV infection.[11]There are over 75 evidence-based risk-reduction strategies identified as successful, including Centering Pregnancy Plus (CPP), Becoming a Responsible Teen (BART), Brief Group Counseling, Communal Effectance: AIDS Prevention (CE-AP), and Female Condom Skills Training.[11]

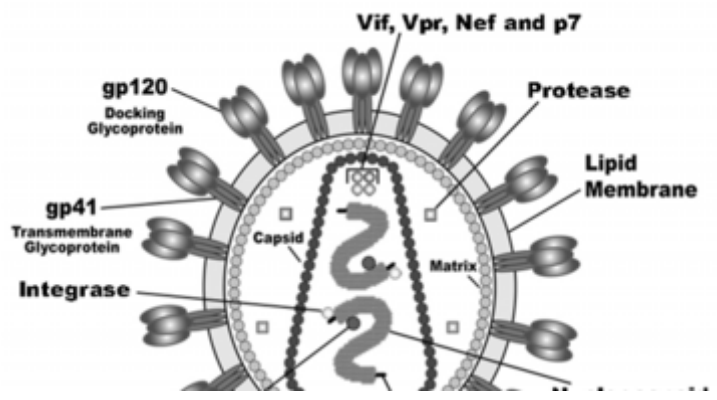
Testing is an important tool in the nation's efforts to curtail the spread of HIV. A person does not know that he or she has HIV unless he or she has been tested. Almost one in six people in the United States who have HIV do not know they are infected.[12]The CDC recommends that healthcare providers test everyone between the ages of 13 and 64 at least once as part of routine healthcare. A person who continues to have unsafe sex or unprotected sex, or who continues to share injection drug equipment, should get tested at least once a year. Sexually active gay and bisexual men may benefit from more frequent testing. Pregnant women should be routinely counseled and voluntarily tested for HIV. Early diagnosis allows a pregnant woman to receive effective antiretroviral therapies for her own health, as well as preventive drugs to improve the chances that her infant will be born free of infection.[13]

Counseling, which should be provided before and after testing, provides a unique opportunity to educate individuals about HIV, how to avoid infection, how to protect others if they are HIV-positive, and options for treatment and follow-up. It also plays a vital role in reducing the transmission of HIV from mother to infant.

PATHOGENESIS AND CLINICAL PRESENTATION OF HIV INFECTION

Pathogenesis of HIV Infection[14,15]

HIV is a double-stranded ribonucleic acid (RNA) virus that uses host cells, particularly CD4 cells, to replicate. HIV is a retrovirus. Normally, DNA produces RNA that is used in protein synthesis in the cell's ribosomes. The infecting virus is able to create viral DNA from the viral RNA using the viral enzyme reverse transcriptase and integrate this viral DNA into the cell's DNA using the viral enzyme integrase.[16]A new virion is produced, which is composed of a nucleoprotein core surrounded by a lipid layer containing viral surface (gp120) and transmembrane (gp41) envelope proteins. The nucleoprotein core contains two copies of viral genomic RNA, viral proteases, and reverse transcriptase (Figure 81-1).



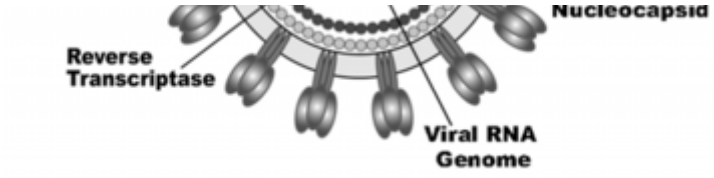


Figure 81-1.

Structure of HIV (National Institutes of Health).

View Image

The critical step in the pathogenesis of HIV disease occurs when the virus envelope protein (gp120) binds to cells carrying the CD4 receptors. The viral RNA can then enter the CD4 cell. The CD4 cells are depleted by a possibly

indirect mechanism not yet fully understood.[17,18] As CD4 cell counts decline, the production of critical lymphokines that support the entire immune system declines. Over time, interleukin-2 (IL-2) production falls. Because IL-2 is critical to the growth and replication of CD4 cells, this results in the collapse of the entire immune system. In patients with HIV infection, the deterioration of the immune system progresses over years. Patients die with advanced disease because of an opportunistic infection or malignancy. The average time from viral transmission to death in patients without treatment is approximately 10 to 12 years. However, there is a widespread variation for individual patients in relation to progression of disease and the time from infection to development of AIDS or death. The two most important predictors of disease progression in patients with HIV are the CD4 cell count and viral load. However, HIV-infected individuals on antiretroviral therapy with a recent undetectable viral load who have maintained or had recovery of CD4 (+) cell counts to at least 500 cells/μL showed no evidence for an increased risk of death compared with the general population.[19]

CD4Cell Count

The normal values for CD4 cell count range from 500 to 1,400 cells/mm^3. The value of CD4 cells is the product of three variables: total white blood cell count, percentage of lymphocytes, and percentage of lymphocytes that bear the CD4 receptor. The CD4 count can vary greatly (up to 25 percent); therefore, single measurements are less helpful than trends. The variation is greater as the CD4 count becomes lower. The CD4 percentage is less variable than the absolute CD4 count. Figure 81-2 depicts the progression of CD4 count in the average patient without treatment.

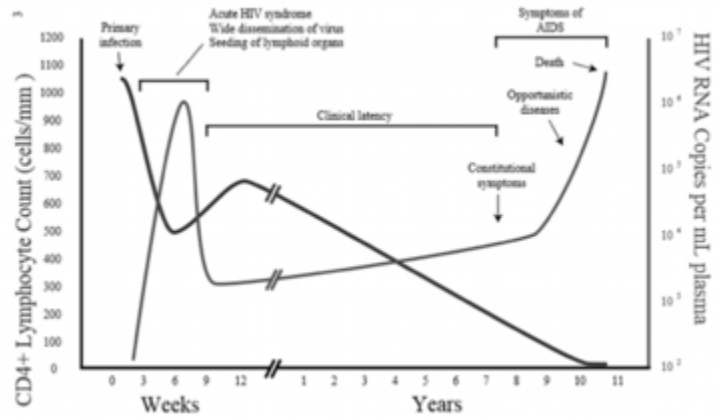

Figure 81-2.

Typical course of HIV infection that shows the relationship between the levels of HIV (viral load) and CD4+ T-cell counts over the average course of untreated HIV infection (Author: Sigve, Used under Creative Commons CCO 1.0 Universal).

View Image

At the moment of transmission the patient starts with a normal CD4 count. This value drops significantly during the first 6 weeks at the time of uncontrolled viral replication. After 3 months of infection, when the patient develops the cellular and humoral response against HIV, there is an improvement in the CD4 count value, but it does not return to preinfection levels. During the following years, the progressive reduction in the CD4 cells is due to the HIV virus killing CD4 cells, as well as a reduced production of CD4 cells. Approximately 3

years after infection, the value of CD4 cells reaches the lower normal level of 500 cells/mm^3. With progression of the disease, the value of CD4 reaches the level of 200 cells/mm^3. Below this value, a patient is considered to have AIDS. The time to development of AIDS or death decreases with a steeper decline in the CD4 cell count. When the CD4 count reaches 50 cells/mm^3, the patient has severe immune suppression. It is not uncommon to see patients with very advanced disease with CD4 values less than 10 cells/mm^3.

Viral Load

A higher viral burden is associated with a more rapid progression of disease. Quantitative determination of the HIV RNA in plasma is used to measure the viral load, or viral burden. Determination of the plasma HIV RNA can be performed in the laboratory using techniques such as HIV RNA PCR, or branched-chain DNA. The tests have a minimal threshold for detection of HIV. The standard tests detect a minimum of 400 copies/mL. New generation tests detect as low as 50 copies/mL. The viral load in HIV patients may range from a value of less than 50 copies/mL, or undetectable, to a value of greater than 750,000 copies/mL.

Figure 81-2 depicts the changes in viral load in an average patient without treatment. At the time of HIV transmission, the host has an undetectable viral load. During the first weeks of infection there is uncontrolled viral replication and the viral load reaches values of 105 copies/mL of plasma. Once the patient develops an immune response to the infection, there is a 2- to 3-log decrease in plasma HIV RNA levels. The viral load stabilizes at a new level, called the "set point." This viral load level dictates the future rate of infection progression. The higher the set point, the more rapidly the patient progresses to AIDS. Even in the absence of antiretroviral therapy (ART), the viral load remains relatively stable over a period of several years. After several years of viral load stability, there is a rapid increase of viral load that is followed by a decrease in CD4 cell counts. During the last stages of the disease, there is uncontrolled viral replication, with viral load levels reaching 106 HIV RNA copies/mL.

Stages of HIV Infection

The natural history of a patient with HIV infection from the time of transmission to death can be divided into the following six stages: (1) incubation period, (2) acute retroviral syndrome, (3) asymptomatic HIV infection, (4) symptomatic HIV infection, (5) AIDS, and (6) advanced HIV infection. The rate of progression from the incubation period to advanced HIV infection in a patient without treatment and the correlation with the CD4 count and viral load is depicted in Figure 81-2. The rate of progression for an individual patient may change significantly from this standard model. A particular patient may rapidly progress to AIDS after 2 to 3 years of infection. On the other hand, some patients may remain asymptomatic with CD counts in the normal range even after 10 years of infection without ART. These patients are called long-term nonprogressors.

Clinical Progression of HIV

1. *Incubation period*: Figure 81-2 depicts the natural history of HIV infection in patients without treatment. The first stage of infection is the incubation period. This period starts with acquisition of HIV and finishes when the patient develops the first clinical

manifestations of HIV infection. In the majority of patients, the incubation period lasts 2 to 4 weeks but in some patients may last for several months. After entering the body, the virus travels to the regional lymph nodes and then enters the systemic circulation. During the incubation period, though the patient is clinically asymptomatic, the virus disseminates primarily to the brain and the lymphatic system, the viral load increases, and the CD4 count decreases.

2. *Acute retroviral syndrome*: After an incubation period of 2 to 4 weeks, the patient develops a complex of symptoms that is called the acute retroviral syndrome. This syndrome is also called acute HIV infection, primary HIV infection, or acute seroconversion syndrome. After viral transmission, the acute retroviral syndrome manifests in approximately 80 to 90 percent of patients. Although the syndrome is commonly severe enough for the patient to seek medical attention, the presence of acute retroviral syndrome may not be recognized by primary care physicians. Patients with the acute retroviral syndrome may present signs and symptoms primarily related to viral multiplication in the lymphatic system (e.g., infectious mononucleosis-like syndrome) or viral multiplication in the central nervous system (e.g., aseptic meningitis syndrome). The duration of the acute retroviral syndrome is less than 2 weeks for most patients. The clinical recovery is associated with development of an immune response to HIV that is associated with a decrease in viral load and increase in CD4 cell count. As part of this immune response, the patient develops antibody titers with positive HIV serology. Determination of the HIV serology test is of no help in the diagnosis of acute retroviral syndrome because at the time the patient is symptomatic the antibody titers are undetectable and HIV serology is negative. During the acute retroviral syndrome there is a high level of HIV viremia with plasma HIV RNA titers of 105 copies/mL. Therefore, when a patient presents with signs and symptoms compatible with acute retroviral syndrome, the laboratory diagnosis is based on the determination of HIV RNA titers or viral load, not determination of HIV serology.
3. *Asymptomatic HIV infection*: During this stage of the disease the patient is clinically asymptomatic. The physical examination of most patients is unremarkable, but some patients may present with persistent generalized lymphadenopathy. During this period, though the patient is asymptomatic, every day there is a significant replication of HIV with destruction of CD4 cells that is partially compensated with an increased production of new CD4 cells. During this asymptomatic stage, there is a persistent decrease in CD4 cells of approximately 30 to 90 cells/mm^3every year.
4. *Symptomatic HIV infection*: After years of asymptomatic infection, the patient starts to develop early symptoms that are related to HIV infection but are not AIDS indicators. Some of these are very unspecific, such as fever or weight loss. This stage was called AIDS-related complex or ARC in the past. In most patients, during this stage the CD4 cell count is in the range of 500 cells/$mm^3$to 200 cells/mm^3. Table 81-1 defines the conditions used to class HIV infections and AIDS.
5. *AIDS*: A patient with HIV infection is considered to have AIDS when the CD4 cell count is less than 200 cells/mm^3or the patient presents with a condition associated with severe immune deficiency. In 1993, the CDC revised the classification system for HIV infection to emphasize the clinical importance of the CD4+ T-lymphocyte count in the categorization of HIV-related clinical conditions. This classification system replaced the system published by the CDC in 1986. Consistent with the 1993 revised classification system, the CDC also

expanded the AIDS surveillance case definition to include all HIV-infected persons who have less than 200 CD4+ T-lymphocytes/uL, or a CD4+ T-lymphocyte percentage of total lymphocytes of less than 14. This expansion included the addition of three clinical conditions: pulmonary tuberculosis, recurrent pneumonia, and invasive cervical cancer—and retained the 23 clinical conditions in the AIDS surveillance case definition published in 1987 used by all states for AIDS case reporting effective January 1, 1993 (Table 81-1).

6. *Advanced HIV infection*: This stage of the disease, also defined as advanced AIDS, applies to patients with CD4 cell counts less than 50 cells/mm^3. At this stage, patients have limited life expectancy even with optimal therapy of HIV infection and opportunistic infections.

Table 81-1. HIV Infection and AIDS: Defining Conditions[20]

Table 81-1 HIV Infection and AIDS: Defining Conditions

Bacterial infections, multiple or recurrent*

Candidiasis of bronchi, trachea, or lungs

Candidiasis of esophagus†

Cervical cancer, invasive§

Coccidioidomycosis, disseminated or extrapulmonary

Cryptococcosis, extrapulmonary

Cryptosporidiosis, chronic intestinal (>1 month's duration)

Cytomegalovirus disease (other than liver, spleen, or nodes), onset at age >1 month

Cytomegalovirus retinitis (with loss of vision)†

Encephalopathy, HIV related

Herpes simplex: chronic ulcers (>1 month's duration) or bronchitis, pneumonitis, or esophagitis (onset at age >1 month)

Histoplasmosis, disseminated or extrapulmonary

Isosporiasis, chronic intestinal (>1 month's duration)

Kaposi sarcoma†

Lymphoid interstitial pneumonia or pulmonary lymphoid hyperplasia complex*†

Lymphoma, Burkitt (or equivalent term)

Lymphoma, immunoblastic (or equivalent term)

Lymphoma, primary, of brain

*Mycobacterium avium*complex or *Mycobacterium kansasii,*disseminated or extrapulmonary†

*Mycobacterium tuberculosis*of any site, pulmonary,†§disseminated,†or extrapulmonary†

Mycobacterium, other species or unidentified species, disseminated†or extrapulmonary†

Wasting syndrome attributed to HIV

*Only among children aged <13 years. (CDC. 1994 Revised classification system for human immunodeficiency virus infection in children less than 13 years of age. *MMWR*1994;43[No. RR-12].)

†Condition that might be diagnosed presumptively.

§Only among adults and adolescents aged ≥13 years. (CDC. 1993 Revised classification system for HIV infection and expanded surveillance case definition for AIDS among adolescents and adults. *MMWR*1992;41[No. RR-17].)

Approximately one-third of new reported cases of AIDS in the United States are based on the finding of a CD4 count less than 200 cells/mm^3, and two-thirds of the reported cases are based on the diagnosis of an AIDS-defining condition. The AIDS-defining conditions reported to the CDC in 1997 and 2008 are listed in Table 81-2.

In 1994–1997, 1998–2002, and 2003–2007, rates of opportunistic infections (per 1,000 person-years) were 89.0, 25.2, and 13.3, respectively, and rates of opportunistic malignancies were 23.4, 5.8, and 3.0. Following the advent of highly active ART (HAART), the opportunistic illness rates declined precipitously and stabilized at low levels in 2003–2007. During that time, there were no significant changes in annual rates of opportunistic infections or opportunistic malignancies; the leading opportunistic illnesses (rate per 1,000 person-years) were esophageal candidiasis (5.2), *Pneumocystis*pneumonia (3.9), cervical cancer (3.5), *Mycobacterium avium*complex infection (2.5), and cytomegalovirus disease (1.8). Thirty-six percent of opportunistic illness events occurred at CD4 cell counts of at least 200 cells/μL.[21]

Table 81-2 AIDS-Defining Conditions As Reported to CDC in 1997 (2003–2007)

• *Pneumocystis jiroveci*	24% (3.9%)
• Wasting syndrome	18%
• Tuberculosis	9%
• Kaposi's sarcoma	7%
• Disseminated *M. avium*	5% (2.5%)
• Chronic herpes simplex	5%
• HIV-associated dementia	5%
• Recurrent bacterial pneumonia	5%
• Toxoplasmosis	4%
• CMV disease	3% (1.8%)

DIAGNOSTIC TEST FOR HIV INFECTION

The original HIV diagnostic testing algorithm was developed by the CDC in 1989.[22]Recently, alterations to the original testing algorithm have been proposed that incorporate advancements made in HIV diagnostic testing, thereby increasing the sensitivity while reducing the turnaround time and cost. In particular, the highly infectious phase of HIV infection (the interval between the appearance of HIV RNA in plasma and the detection of HIV-1 antibodies) contributes disproportionately to HIV transmission. To address this problem, the CDC has been evaluating a new HIV diagnostic algorithm soon to be released that will reduce the risk of interpreting results erroneously as negative.[22]

1. *Standard serologic tests:*The most commonly used laboratory test for diagnosis of HIV infection is the serologic detection of antibodies to the virus. The standard serologic test

consists of a screening enzyme immunoabsorbent assay (EIA) followed by a confirmatory Western blot (WB). In a patient with a positive EIA test, the test should be repeated. In a patient with a repeatedly positive EIA test, a confirmatory WB is performed. These serologic assays show sensitivity and specificity rates of 99.9 percent.

There is always a delay from the time of infection until the patient develops positive serology. After transmission of the virus, most patients develop antibodies at the time that there is clinical resolution of the acute retroviral syndrome. This time delay, called the window period, averages 21 days but in some patients may extend for several months. If serologic testing is performed during the window period, the test will be negative in a patient who is infected with HIV. Serologic testing during the window period produces a false-negative result.

2. *Viral load*: When a physician considers that a patient may have an acute retroviral syndrome, the HIV serology is of no diagnostic value, as the patient is still in the window period. In this clinical scenario, the diagnosis of acute HIV infection is performed by determination of quantitative HIV RNA (viral load). During the incubation period of HIV infection and during the acute retroviral syndrome, the antibody tests are negative but the patient has high levels of HIV RNA in plasma. RNA tests detect the virus directly (instead of the antibodies to HIV) and thus can detect HIV at about 10 days after infection—as soon as it appears in the bloodstream and before antibodies develop. These tests cost more than antibody tests and are generally not used as a screening test.[22]
3. *Rapid HIV tests*: The FDA approved a rapid test for diagnosis of HIV infection that can offer a result in 15 minutes. A negative rapid test is reported as a definitive negative HIV test. A reactive test result needs to be confirmed with standard serologic tests. The rapid test has been used for determining the serologic status of the source in healthcare personnel (HCP) exposures and for pregnant women who present in labor and have not been previously tested. The use of rapid HIV testing for counseling purposes is increasing.[23]

Follow-up diagnostic testing is performed if the first immunoassay result is positive. Follow-up tests include an antibody differentiation test, which distinguishes HIV-1 from HIV-2; an HIV-1 nucleic acid test, which looks for virus directly; or the WB or indirect immunofluorescence assay, which detect antibodies.

Immunoassays are generally very accurate, but follow-up testing allows the patient and his or her healthcare provider to be sure the diagnosis is right. If the first test is a rapid test, and it is positive, the patient is directed to a medical setting to get follow-up testing. If the first test is a lab test, and it is positive, the lab will conduct follow-up testing, usually on the same blood specimen as the first test.

False-positive tests are rare. If tests are conducted during the window period, they can give a false-negative result.

*In-home tests:*Currently there are only two home HIV tests: OraQuick In-home HIV test and the Home Access HIV-1 Test System. The HIV test should be FDA-approved.[24]

TREATMENT OF HIV INFECTION

Goals of Antiretroviral Therapy

The primary goals for initiating ARV therapy are to:

- Reduce viral load as much as possible for as long as possible.
- Reduce HIV-associated morbidity and prolong the duration and quality of survival.
- Restore and preserve immunologic function.
- Maximally and durably suppress plasma HIV viral load.
- Prevent HIV transmission.

The viral suppression allows immune reconstitution that translates to increased number of CD4 cells and a better pathogen-specific immune response. Then, with appropriate therapy, the patient will have a decreased viral load, increased CD4 count, and decreased risk for opportunistic infections. This will translate to improved quality of life and prolongation of life.

Although ARV therapy has clear benefits, there are some drawbacks. All drugs have side effects; therapy usually involves taking several drugs multiple times a day, and compliance with the regimen must be strict to prevent development of viral resistance. Because viral resistance to a drug may produce cross-resistance to other drugs, development of resistance to a current regimen may render future antiretroviral therapy ineffective. Thus, HIV drug-resistance testing is recommended in persons with HIV infection at entry into care regardless of whether ART will be immediately initiated or deferred.[24]

Medications

In 1987, a drug called AZT became the first approved treatment for HIV disease. Since then, over 30 drugs categorized in six different classes have been approved to treat people living with HIV/AIDS, and more are under development. Antiretroviral drugs used in the treatment of HIV infection are listed on the FDA website (http://www.fda.gov/).

These drugs may be called by many different names, including:

- "The cocktail"
- Antiretrovirals (ARVs)
- Highly active antiretroviral therapy (HAART or ART)

Taking three different HIV medications is more effective than taking one medication because each class of drug attacks the virus at a different point in its life cycle. Taking more than one drug also helps protect against HIV drug resistance.[25]

HIV Life Cycle and Antiretroviral Targets

Using the gp120 surface glycoproteins, HIV attaches to the CD4 cellular receptors and coreceptors and penetrates the cells. Drugs that block the attachment of the virus are known as entry inhibitors or fusion inhibitors. Once inside the cell, the viral RNA is transformed to viral

DNA by the viral enzyme reverse transcriptase. This represents an important target site during the HIV life cycle. There are currently two classes of ARV drugs that act at this level, the nucleoside and nucleotide reverse transcriptase inhibitors and the non-nucleoside reverse transcriptase inhibitors. Following the transcription from RNA to DNA, the viral DNA moves to the nucleus of the cell and integrates to the host cell DNA in the chromosomes, producing a lifelong infection. Using host cell enzymes and ribosomes, the transcription and translation of proviral DNA produces new HIV proteins. These newly produced HIV proteins are made as polyproteins. One essential step during the last stage of assembly and release of the new virus is the modification of viral polyproteins by specific enzymes such as HIV proteases. This represents another target for ART. Drugs that act at this level are known as protease inhibitors.

Specifically, the six classes of ARV are described as:

- *Nucleoside/nucleotide reverse transcriptase inhibitors (NRTIs)*act as faulty building blocks in production of viral DNA production. This blocks HIV's ability to use reverse transcriptase to correctly build new DNA that the virus needs to make copies of itself.
- *Non-nucleoside reverse transcriptase inhibitors (NNRTIs)*act directly on reverse transcriptase to prevent it from functioning correctly.
- *Protease inhibitors (PIs)*block the protease that cuts long strands of genetic material created by the virus and prevent those long strands of genetic material from being cut up into functional pieces.
- *Fusion inhibitors*block HIV from entering the cells. Fusion inhibitors can target the sites on either HIV or CD4 cells and prevent HIV from "docking" into healthy cells.
- *Entry inhibitors-CCR5 co-receptor antagonist*inhibits or blocks HIV from cell entry using the CCR5 receptor.
- *HIV integrase strand transfere inhibitors (INSTI)*block the process of reverse transcription (by blocking the HIV enzyme integrase) and prevent the virus from adding its DNA into the DNA in the CD4 cells. Preventing this process prevents the virus from replicating and making new viruses.

What Drugs to Start

Guidelines for the use of ARV agents in HIV-infected adult, adolescent, pediatric, and perinatal cases are under constant review and scrutiny as new evidence is released. Because the practice of ART is very specialized and complex, providing specifics on therapy is beyond the scope of this chapter. Most up-to-date guidelines for the use of ARV agents in adults, adolescents, and special populations are published by the National Institute of Health (NIH).[26]

When to Start Therapy

Considering the risk and benefits of ART, the decision to start therapy must be individualized. Factors that must be considered in the decision are the patient's willingness and readiness to initiate therapy, the availability of resources, and any comorbid conditions. Although controversy still exists among experts regarding when to start therapy in a patient who is asymptomatic, the NIH recommends initiating treatment in all HIV-infected individuals as soon as diagnosed as long as the patient is committed to therapy for an indefinite period of time. Initiating ART early in

disease progression inhibits HIV replication so that plasma HIV RNA levels (viral load) remain low. In addition, durable viral suppression improves immune function and lowers the risk of both AIDS-defining and non-AIDS defining complications, prolonging life.[25]

Treatment During Pregnancy

If mothers have HIV, infants can become infected during pregnancy, during labor and delivery, and to a lesser degree during breast-feeding. If the pregnant woman who has HIV is treated with ARV agents during pregnancy and labor, the risk of passing HIV to the infant is reduced drastically.[27]Thus, all pregnant women should be offered HIV testing. If an HIV-infected pregnant woman has already been on ART, therapy should be continued. Because of concerns about teratogenicity, efavirenz should not be used in women who are planning pregnancy or during the first trimester of pregnancy.

Trends in AIDS incidence among children continue to demonstrate the dramatic success of efforts to reduce perinatal (mother-to-child) transmission. Clinical trials showed that HIV-infected women could reduce the risk of transmitting the virus to their babies by as much as two-thirds through administration of zidovudine (AZT), which is known to cross the placenta. AZT is given to HIV-infected mothers during their last two trimesters of pregnancy, through labor, and then to their babies for 6 weeks after birth. Infected mothers do not always seek prenatal care, so it is not always possible to provide the full course of treatment. Even if only given after birth, AZT appears to substantially reduce the chances of vertical transmission of HIV to newborns. For the purpose of preventing perinatal transmission of HIV, ART is indicated in all pregnant women regardless of viral load, CD4 count, or clinical status.

Prevention of Opportunistic Infections

The prevention of opportunistic infections is an important aspect of the clinical management of patients with HIV. The use of HAART has led to decreased morbidity and improved survival in patients with AIDS. The CDC, the NIH, and the HIV Medicine Association of the Infectious Diseases Society of America have published guidelines for the prevention and treatment of opportunistic infections in HIV-infected adults and adolescents.[28]

RISK FOR HIV TRANSMISSION IN THE HEALTHCARE SETTING

Risk for HIV Transmission to Patients

Although there is the possibility of transmission from patient to patient or from HCP to patient, it is extremely rare. In 1990, the CDC described the first case of HIV transmission from HCP to a patient (dentist to patient). In total, five cases of HIV transmission were suggested.[29]All cases had strains that were genetically similar to the dentist's strain. This case generated much anxiety on the part of patients. However, even with numerous look-back studies involving thousands of patients cared for by HIV-positive HCP, only three additional cases have been reported: (1) probable transmission from an orthopedic surgeon to a patient in France; (2) probable transmission from a nurse to a patient, also in France; and (3) probable transmission from a gynecologist to a patient during a cesarean delivery in Spain. Currently, the CDC recommends

that HCP use Standard Precautions to prevent HCP-to-patient as well as patient-to-HCP transmission.

In the healthcare setting, there is the possibility of transmission from patient to patient, though the risk is extremely limited. The greatest risk for patient-to-patient transmission is during invasive procedures when instruments or syringes are reused without effective cleaning and sterilization between uses. Infection preventionists must ensure that FDA guidelines are strictly enforced to prevent this occurrence (see www.fda.gov for guidelines on reprocessing of single-use devices; also see Chapter 32 Reprocessing Single Use-Devices).

Risk for HIV Transmission from Patients to Healthcare Personnel

As of December 2010, the CDC is aware of 57 HCP in the United States who have been documented as having seroconverted to HIV after occupational exposures. Of these, 26 developed AIDS. When the very high number of caregivers with a high rate of exposure is considered, this number, though regrettable, represents an extremely low occurrence of the disease. These individuals who seroconverted included 24 nurses, 19 laboratory workers (16 of whom were clinical laboratory workers), 6 physicians, 2 surgical technicians, 1 dialysis technician, respiratory therapist, 1 health aide, 2 housekeeper/maintenance workers, and 1 embalmer/morgue technician.[30]It is interesting to note that this number has not increased since reported in 2002.

The risk for HIV transmission from a single percutaneous exposure to HIV-positive blood is estimated to be 0.3 percent to 0.4 percent. The risk after mucous membrane exposure is on the order of 0.09 percent.[31]

Recommendations to Prevent Transmission

In 1985 and 1986, the CDC published recommendations to prevent the transmission of HIV in the workplace. In 1987 and again in 1998, more comprehensive documents were published in response to increasing concern from HCP about occupational exposure to HIV. In September 2013, the CDC again published recommendations, entitled *Updated U.S. Public Health Service Guidelines for the Management of Occupational Exposures to Human Immunodeficiency Virus and Recommendations for Post-exposure Prophylaxis*.[32]

All of these documents continue to stress the importance of applying blood and body fluid precautions to all patients and designated this policy Standard Precautions (see Chapter 28 Standard Precautions and Chapter 105 Minimizing Exposure to Blood and Body Fluids).

MANAGEMENT OF OCCUPATIONAL EXPOSURES

The most current recommendations for management of occupational exposures to HIV are included in *Updated U.S. Public Health Service Guidelines for the Management of Occupational Exposures to Human Immunodeficiency Virus and Recommendations for Post-exposure Prophylaxis*.[32]Infection preventionists and occupational health professionals are referred to this document for recommendations for post-exposure prophylaxis (PEP).

Healthcare organizations should have a policy and readily accessible protocol for postexposure management. A method for providing evaluation of an exposure event as well as a rapid response process must be addressed in the facility plan. Occupational exposures should be considered urgent medical events to ensure timely postexposure management.

The first action after exposure involves an immediate first aid to the exposed site, including cleaning of the exposed/injured site. A soap-and-water hand wash should be performed to remove visible proteinaceous material. Alcohol is virucidal, so an alcohol-based hand hygiene agent can be used after soap-and-water hand wash has been performed. Caustic chemicals such as bleach should not be used in an attempt to disinfect or cleanse the skin. Squeezing or "milking" the injured site is not necessary. Once the area has been washed, evaluation by a skilled professional should be sought. Chapter 101 Occupational Exposure to Bloodborne Pathogens addresses postexposure management in detail.

Consultation with local experts and/or the National Clinicians' Postexposure Prophylaxis Hotline (PEPline, 1-888-448-4911) is advised when the source person's virus is known or suspected to be resistant to one or more of the drugs considered for the PEP regimen. Other indications for consultation with experts include delayed exposure report, unknown source person, or pregnancy in the exposed person.

ETHICAL AND LEGAL ISSUES FOR HEALTHCARE PERSONNEL CARING FOR PATIENTS WITH HIV

HIV Testing

The CDC recommends that healthcare providers test everyone between the ages of 13 and 64 at least once as part of routine healthcare. Almost one in five people in the United States who have HIV do not know they are infected.[13]After the transmission of HIV by the Florida dentist and Australian and French surgeons, the general public has voiced concern regarding the risk of transmission of infection from HCP. The Society of Hospital Epidemiologists of America (SHEA) recommends restrictions in practice for HIV-positive HCP who have greater than $5X10^2$genome equivalents.[33]

Every patient is considered a potential risk. By using Standard Precautions, protection is provided and there is no need to know the patient's HIV status as it pertains to treatment, except to protect the possibly immunocompromised patient.

Caring for Patients with HIV

Working with patients who are facing an illness with a long unpredictable course and fatal outcome, caregivers have the opportunity to facilitate the patient's role as an active participant in his or her health, work, family, and community. Caring for patients with HIV can be exceptionally rewarding and, at the same time, frustrating and stressful. Stressors arise from specific issues directly related to HIV and from more general concerns of a chronic illness in an environment of limited resources. By recognizing positive and difficult aspects of HIV care, HCP can be more effective in caring for the needs of both patients and themselves.

Attitude and behavior adjustments need to be made through education concerning prevention, transmission, and treatment of HIV. Courses and training programs have had remarkable success in AIDS/HIV education and for dispelling myths and misconceptions concerning HIV.

HCP who work for hospitals, home health agencies, or walk-in clinics, along with their employers, generally lack legal backing to deny care to a patient with HIV/AIDS or any "infectious" disease. Refusing to care for a patient could result in dismissal. Requests for different assignments may be made, but an employer is not obligated to honor the request. In certain circumstances, policy may permit temporary reassignment for an immunosuppressed HCP to decline care of infected clients. Any policy must be applied consistently and fairly.

Public policy in the area of HIV/AIDS issues continues to progress. HCP are counseled to keep current with laws and court rulings in the state, as well as employment policies and procedures.

DISCRIMINATION AGAINST PATIENTS WITH HIV INFECTION

The Americans with Disabilities Act (ADA) of 1995 identifies HIV as a disability. This affords patients infected with HIV special protection under federal law. This assists with discrimination in the workplace, when dealing with housing issues, and in social and medical services.[34]

Signed into law on July 26, 1990, the ADA is wide-ranging legislation intended to make U.S. society more accessible to people with disabilities. The ADA's protection applies primarily, but not exclusively, to disabled individuals. One is considered disabled if he or she meets at least any one of the following criteria: he or she has a physical or mental impairment that substantially limits one or more of his or her major life activities; he or she has a record of such an impairment; he or she is regarded as having such impairment. The ADA protects patients with infectious diseases from discrimination in access to services and employment. The duty to treat in regard to healthcare facilities that receive Medicare and other federal funds also applies.

It was reported in June 25, 1998, that HIV-infected people are protected by the federal ban on discrimination against disabled persons even if they have no symptoms of AIDS.[34,35]The ruling went against a Maine dentist who told an HIV-infected patient that he would fill her cavity in a hospital but not in his office. The woman sued under the ADA, a federal civil rights law that bars disability discrimination.

This landmark decision was a victory not just for people with disabilities, but also for the Justice Department, which included people with HIV under the scope of this law. This federal law also protects those with disabilities in regard to employment issues, public accommodations including hospitals and clinics, and access to medical treatment. Title III, which is the most far-reaching ADA title in a healthcare context, prohibits discrimination by enterprises that are considered places of public accommodation. Title III classifies private healthcare services as a public accommodation without regard to whether service providers are considered recipients of federal financing.

KNOWLEDGE REGARDING A PATIENT'S HIV/AIDS STATUS[36]

Employers, healthcare providers, and other individuals have expressed much doubt and uncertainty about whether they have a right or obligation to disclose the status of an individual known to them to be HIV infected to others with whom the individual may come into contact. This issue must be examined critically as current law reflects rational, thoughtful consideration of the need to know in certain circumstances. It is forbidden to disclose this information except in limited circumstances.

Most people with HIV face, at least briefly, some issue regarding public knowledge of their status. They deal with discrimination in obtaining employment and insurance. Knowledge of their status may touch other parts of their lives, such as custody of children or maintaining personal relationships. In the long run, only adequate public education will help solve these problems.

Laws that govern who should have knowledge of a patient's HIV/AIDS status are obscure at times. One thing is clear: anyone who reveals information about a patient's HIV status could face both civil liability and disciplinary action for unauthorized disclosure of confidential information under the Health Insurance Portability and Accountability Act (HIPAA). The Office of Civil Rights (OCR), in the Department of Justice, enforces the HIPAA Privacy and Security Rules, a set of federal standards to protect the privacy and security of patients' medical records and other health information maintained by covered entities: health plans; most doctors, hospitals, and many other healthcare providers; and healthcare clearinghouses. These standards provide patients with access to their medical records and exert significant control over how their personal health information is used and disclosed. Persons with HIV/AIDS who believe that their health information privacy rights have been violated may file a complaint with OCR.

There are legal statutes that determine who can be forced to take an HIV test, have tests taken without their knowledge, or results revealed against their will. Similarly, statutes exist that offer general control over medical records, which may directly or indirectly reveal a person's HIV status, and federal and state constitutional protection of privacy in the face of government intrusion.

Unless they have given explicit permission, a patient's health status should not be discussed with anyone other than direct caregivers, doctors, or the patient. HCP should check with the facility's risk manager or a supervisor to ascertain who is authorized to inform those who need to know.

When consent is needed to disclose health information, it should be made in writing. It must specifically indicate what information will be released, to whom, and for how long the consent is valid. In releasing HIV-related data, a statement should be included that prohibits the receiving party from further disclosing the information without the patient's evidence of consent.

HCP should not discuss health issues in public areas where others may overhear. When giving HIV-related instructions to a patient, HCP should take that patient to a private room. Any incident in which it is suspected that health information has been disclosed improperly or without authorization should be reported.

REPORTING TO THE PUBLIC HEALTH SYSTEM

Physicians, hospitals, and laboratories must promptly report both HIV-positive patients and confirmed cases of AIDS to the public health service in accordance with their state reportable diseases laws. Unless tested anonymously, patients must be identified by name and other information provided for statistical purposes; however, cases of asymptomatic HIV infection may be reported by initials or code numbers in lieu of a name. It is essential to know local law and policies that impact HIV care delivery and to establish a relationship with the individuals responsible for this reporting.

HUMAN SERVICES AVAILABLE FOR HIV PATIENTS

A number of social services are available to individuals with HIV. This is a chronic disease. The ability of the individual to maintain an optimal level of health is dependent upon the ability to continue medical care as well as have basic needs met. It is important that infection preventionists be aware of the care coordination and that other human, social, and faith-based services be available for individuals with HIV/AIDS so this information can be readily available for those in need.

Conclusions

Although infection with HIV has no cure, key components of a HIV prevention program center on the use of Standard Precautions in healthcare settings, risk reduction through behavioral modification programs, and medication adherence programs. Progress has been made in diagnostic testing during the highly infectious period, the window state, and testing for HIV-resistant patterns. Even though an HIV vaccine has not yet been successful, there has been advancements in the study of PEP for people who are at high risk of getting HIV.[37]Education is the most effective method to promote risk reduction; it should include information about the infection, modes of spread, and prevention. The application of a bloodborne pathogen prevention plan including Standard Precautions is still the most important infection prevention strategy to prevent workplace transmission. Reporting requirements for HIV infection and AIDS vary based on locality and applicable laws.

APIC TEXT OF INFECTION CONTROL AND EPIDEMIOLOGY

Influenza

Author(s): Hilary Babcock, MD
Instructor, Infectious Diseases

Washington University School of Medicine
St. Louis, MO

Published: October 3, 2014

Abstract

Influenza viruses are responsible for acute respiratory illnesses during winter seasons in temperate climates. Epidemic influenza occurs due to small changes in surface glycoproteins, a process known as antigenic drift. Large changes in those proteins, known as antigenic shift, are responsible for larger pandemic influenza outbreaks. Seasonal influenza is expected annually, but the threat of pandemic influenza due to a large change in seasonal strains or introduction of a novel strain requires infection prevention and control programs to have surveillance, interventions, and emergency preparedness plans in place. Influenza can cause a spectrum of disease in humans, ranging from a self-limited respiratory infection to a more fulminant illness. The very young and very old are more susceptible to severe disease, as are individuals with certain underlying medical conditions. Several antiviral drugs are available for treatment of influenza, but vaccination and respiratory etiquette are the primary control strategies. Each year, vaccines are modified to reflect the strains most likely to be circulating.

Key Concepts

- Influenza is a contagious respiratory disease transmitted from person to person primarily via virus-laden droplets.
- Outbreaks of healthcare-associated influenza can occur and affect both patients and healthcare personnel.
- Vaccination is the primary method for preventing influenza and its complications.
- Healthcare personnel compliance with annual influenza vaccination is an expected behavior to protect patients, staff, and families.
- Standard Precautions including respiratory hygiene and cough etiquette and Droplet Precautions are effective infection prevention methods used to prevent influenza transmission in healthcare facilities.

- Influenza prevention plans include education, vaccination, isolation, and surveillance, as well as restricting visitors and healthcare personnel who are ill and enhancing infection prevention measures during outbreaks.

Background

Influenza epidemics in the United States result in an average of 3,300 to 48,000 deaths[1] and more than 200,000 hospitalizations annually. Infection rates are highest among children, but serious illness and death occur predominantly among individuals 65 years old and older and individuals who have certain medical conditions, such as chronic pulmonary or heart diseases.[2,3,4,5] Influenza pandemics occur episodically, the most recent in 2009 when a novel 2009 influenza A (H1N1) was identified as causing illness in at least 191 countries.[6] Vaccination is the primary method for preventing influenza and its complications, and recommendations for vaccine and antiviral drug use are published regularly by the Advisory Committee on Immunization Practices (ACIP).[7] Information regarding influenza surveillance and control is available on the Centers for Disease Control and Prevention (CDC) website, through the CDC Voice and Fax Information systems, and on the CDC website **http://www.cdc.gov/flu/**. (See Supplemental Resources.)

Basic Principles

EPIDEMIOLOGY

Influenza is primarily spread between individuals via respiratory secretions (droplet spread). Viral shedding can start 24 to 48 hours after infection, and typically 24 hours before the onset of symptoms.[8] Shedding normally persists 5 to 7 days but can be 10 days or longer in children and the immunocompromised.[8,9] Thus, most adults are considered infectious from the day before symptoms begin until approximately 7 days after the onset of illness.

CLINICAL MANIFESTATIONS

Influenza can manifest in a variety of ways, ranging from asymptomatic infection to prostration in more severe cases. Upper respiratory symptoms tend to occur most frequently, along with systemic symptoms of fever, headache, and myalgia, most often with acute onset. Although these symptoms are common in influenza, they are not specific for influenza since they are also common in other viral respiratory illnesses.[10,11,12] Establishing the diagnosis of influenza, as opposed to a respiratory illness due to another virus, remains an important clinical challenge.

In addition to the typical manifestations described, the illness may present differently in young children, the elderly, and immunocompromised individuals. Children may present with otitis media and young children may exhibit initial symptoms reminiscent of bacterial sepsis with high fevers and febrile seizures.

In elderly patients with influenza, fever and cough remain frequent findings although the temperature elevation might be blunted compared with younger patients.[13] Underlying illnesses and medications may mask symptoms in hospitalized patients. Therefore, absence of influenza-like symptoms does not

effectively rule out influenza, and high clinical suspicion must be maintained during the appropriate season.[12]

COMPLICATIONS OF INFLUENZA

The patients at highest risk of developing complications and requiring hospitalization from influenza include children younger than 5 years, patients 65 years or older, pregnant women, obese patients, and those with chronic underlying medical conditions. The most significant medical condition associated with development of complications is asthma, but other pulmonary, cardiac, hematologic, metabolic, and neurologic conditions also increase the risk of complications.[14,15,16]During the influenza A 2009 (H1N1) pandemic, previously healthy younger adults had an increased incidence of complications.

Viral Pneumonia

Influenza pneumonia is usually bilateral and unassociated with isolation of typical bacterial pathogens, although influenza virus may be isolated from sputum. The mortality can be high, and treatment with antiviral medications (discussed later in this chapter) is appropriate. Pneumonia is more common in older adults with comorbidities. Patients with pneumonia are symptomatic longer than patients without pneumonia.[17]Influenza pneumonia can also occur in younger patients, especially during pandemics as seen with influenza A 2009 (H1N1) when a mean age as low as 32 years was observed in one center.[18] Up to 70 percent of critically ill patients can have hypoxia with diffuse patchy opacities seen in a chest roentgenogram.[19,20]

Bacterial Coinfection

During the influenza epidemic of 1918 to 1919, secondary bacterial pneumonia was the most common cause of death.[21]During the 2009 pandemic influenza A (H1N1), up to 30 percent of patients managed in intensive care units (ICUs) had documented bacterial coinfection, defined as bacterial pneumonia or bacteremia.[22]The number increased up to 55 percent of patients in autopsy series when reviewing fatal cases.[23]Bacterial pneumonia usually complicates influenza infection 4 to 14 days after improvement in initial symptoms and presents with fever and productive cough. In severely ill patients bacterial coinfection can develop as early as 5 days after the onset of influenza symptoms.[22]

*Staphylococcus aureus*is the most common cause of bacterial coinfection, in particular pneumonia, closely followed by *Streptococcus pneumoniae*and *Streptococcus pyogenes*. Other healthcare-associated pathogens have also been implicated in severely ill patients. Community-associated methicillin-resistant *S. aureus*has been reported as the causative agent of severe necrotizing community-associated pneumonia associated with influenza, even in patients without underlying comorbid medical conditions. On January 30, 2008, the CDC issued a health alert on influenza-associated pediatric mortality and*S. aureus*coinfection. It was recommended that healthcare providers be alert to the possibility of bacterial coinfection among children with influenza and request bacterial cultures if children are severely ill or if community-associated pneumonia is suspected.[24]The CDC conducts annual surveillance for pediatric deaths associated with influenza.

Rare Syndromic Complications

Influenza infection has been associated with encephalitis, transverse myelitis, Reye's syndrome, myositis, myocarditis, pericarditis, and renal failure.[25,26,27]

VIRUS IDENTIFICATION AND CHARACTERIZATION

Influenza viruses are divided into three categories, designated A, B, and C. All three contain negative-sense, segmented, single-strand RNA molecules. The influenza A viruses are the most common clinical isolates, and they are further subdivided by differences in two surface proteins: hemagglutinin (H) and neuraminidase (N). Three H and two N antigenic subtypes account for virtually all human infections. The most prevalent influenza A strains in humans in the last 30 years have been H3N2 and H1N1. In recent years, influenza A and B strains also have been named according to the city or state and year of their initial isolation, for example, A/Texas/36/91 (H1N1) or B/Hong Kong/330/2001. Influenza A strains are the predominant cause of pandemics. Influenza B strains can also cause annual epidemic disease, but the clinical illnesses tend to be milder than illnesses caused by influenza A. Influenza C strains can be identified in up to 13 percent of influenza infections, but they either produce mild illness (usually a "common cold") or are detected with another respiratory virus which makes it difficult to asses its clinical role.[28]Influenza C strains have not been associated with large epidemics.[29]

Non-human Reservoirs

Influenza A viruses infect many different animals, most notably swine and poultry, who serve as reservoirs and can occasionally be transmitted between human and animal species. The H5, H7, and H9 strains preferentially infect birds but can spread to humans.

An H5N1 avian influenza strain was recovered during an outbreak in Hong Kong in 1997 that killed six people. It was contained with aggressive control measures but recurred in humans in 2003. Now labeled highly pathogenic avian influenza A (HPAI H5N1), it has been circulating in Asia, Africa, the Pacific, Europe and the Near East with more than 600 human cases reported to the World Health Organization (WHO). The HPAI H5N1 strain is transmitted readily between birds and from birds to humans and only rarely transmitted between humans. It causes significant mortality in affected individuals.[30,31]A new avian influenza A (H7N9) causing human infections was reported in China on April 1, 2013. It caused severe respiratory disease in humans, with high rates of admission and death.[32]The outbreak was contained and no human-to-human transmission was reported.

Swine influenza A strains are usually H1N1, H3N2, and H1N2. They cause outbreaks of influenza in pigs, and sporadically human infection. They are often referred to as "variant viruses" when this happens. Influenza H3N2v are strains that normally circulate in pigs, but occasionally cause infection in humans, most commonly associated with exposure to pigs at agricultural fairs during summer months in the United States.[33]

The new virus that caused the 2009 pandemic, now labeled "2009 H1N1 influenza," was carried by genetic elements closely related to swine H1N1, but never found among U.S. pig herds. It also contained avian elements. This strain is now one of the annual circulating influenza strains.

DIAGNOSIS

Influenza can be diagnosed in a variety of ways. Clinical diagnosis relies on symptoms suggestive of influenza, including upper respiratory symptoms with fever and myalgia. However, in influenza season, a high degree of suspicion should be maintained as not all patients have classic influenza-like illness (ILI) symptoms.[12]

Commercially available rapid influenza diagnostic tests (RIDTs) are designed for antigen detection directly from nasopharyngeal swabs. They have modest sensitivity (40 to 70 percent) but are highly

specific (90 to 95 percent).[34]The performance of RIDTs varies based on seasonality when influenza viruses are circulating in the community. Immunofluorescence antibody testing may increase the sensitivity of the assay. However, neither a negative fluorescent antibody test nor RIDT provide sufficient evidence to rule out the clinical diagnosis of influenza.

Influenza A and B viruses propagate well in tissue culture (e.g., Madin Darby canine kidney, a continuous cell culture line also known as MDCK cells, and primary monkey kidney cells). Many (but not all) influenza isolates produce cytopathic effect in tissue culture, which may be detected microscopically. Reverse transcription-polymerase chain reaction (RT-PCR) is increasingly used where available for its high sensitivity and rapid turnaround time. RT-PCR has become the gold standard for the diagnosis of influenza. It has higher sensitivity than culture and can also be used to differentiate between influenza types and subtypes.[35]

If there is clinical suspicion of influenza infection in a hospitalized patient, then empiric treatment should be initiated. Only culture and PCR are sensitive enough to rely on for ruling out influenza infection, and thus for removing suspected influenza patients from Droplet Precautions.

A good review of laboratory diagnostics for influenza, including rapid influenza tests, can be found on the CDC's "Seasonal Flu" website under "Guidance for Clinicians on the Use of Rapid Influenza Diagnostic Tests," which is available online at: **http://www.cdc.gov/flu/professionals/diagnosis/clinician_guidance_ridt.htm**.

TREATMENT

The treatment of influenza includes supportive measures for all cases and antiviral therapy in certain cases. There are four antiviral agents for the treatment and prevention of influenza. Amantadine and rimantadine work by blocking the viral M2 protein ion channel.[36]However, these older agents are not currently recommended in the United States due to increased resistance. The neuraminidase blockers oseltamivir and zanamivir are the preferred antivirals and work by inhibiting viral release after replication in infected cells. They have activity against both influenza A and B, and resistance among circulating viruses is currently low but does vary by strain. Currently, neuraminidase inhibitor can be used for treatment and prophylaxis of influenza. Resistance can emerge rapidly, however, and clinicians should review annual recommendations on antiviral treatment to ensure appropriate use.

Most healthy outpatients with influenza will recover with supportive measures alone and do not require antiviral treatment. However, antiviral treatment should be initiated promptly in a patient who meets any of the following criteria:

1. Hospitalized
2. Severe, complicated, or progressive disease
3. High risk for influenza complications
   - Age <2 or >65
   - Immunosuppressed
   - Pregnant
   - Morbid obesity
   - Chronic care facility resident
   - American Indians/Alaska Natives
   - <19 years on chronic aspirin

- Other chronic medical problems as mentioned before.

Treatment with oseltamivir and zanamivir should be started as early as possible, when indicated. Early treatment has been shown to shorten the duration of illness and hospitalization and may also reduce the risk of complications and death. The benefit is greater the earlier therapy is initiated. Most data suggest that starting therapy within 48 hours of initiation of symptoms reduces the duration of illness. However, in multiple studies performed during and after the influenza A 2009 (H1N1) pandemic, there appeared to be benefit from treatment even beyond the 48 hours after symptom onset. These studies found benefits such as reducing the duration of symptoms, duration of hospitalization, complications, respiratory failure, and death even when antiviral therapy was initiated up to 5 days after symptom onset.[37,38,39,40]The impact of antiviral treatment in severely ill patients is not entirely clear, but treatment is usually recommended in that setting.

PREVENTION AND CONTROL: ANNUAL INFLUENZA VACCINATION

The severity of most influenza epidemics is influenced by the degree of immunity in the population. Clinical studies have shown that protection from influenza infection is primarily strain specific (i.e., antigen specific). Influenza vaccination is the preferred method for preventing influenza and its complications in individuals. A more subtle benefit that accrues from individual vaccination is herd immunity, which occurs when enough people in a community are immunized, then it is more difficult for the infection to reach people who are not immunized, or do not respond to the vaccine. The immunized population protects the nonimmune by lowering the prevalence of infection in the community.

Starting in 2010, the ACIP recommend that all persons aged 6 months and older should receive routine annual influenza vaccine. Vaccinating individuals before the seasonal increase in influenza virus circulation is the most effective means of reducing the incidence and complications of influenza. Vaccination is far more cost effective than chemoprophylaxis with antiviral agents after exposure.[41,42]

Vaccination coverage can be increased by administering the vaccine during hospitalizations or during routine healthcare visits before the influenza season. Vaccination of healthcare personnel (HCP) and others in close contact with individuals at high risk for severe influenza illness and its complications can reduce transmission of influenza. When vaccine supply is limited, vaccination efforts should focus on persons at high risk for medical complications due to influenza and their close contacts, described as follows:

1. All children 6 months to 18 years of age, and all adults 50 years of age and older.
2. Adults and children with underlying medical conditions, including cardiovascular, renal, pulmonary, metabolic (including diabetes), hematologic, and neurologic disorders; morbid obesity; and children receiving long-term aspirin therapy who might be at risk for Reye's syndrome if infected with influenza.
3. Adults and children who are immunosuppressed.
4. Pregnant women and breastfeeding mothers.
5. Residents of long-term care facilities.
6. Household contacts of anyone meeting the above criteria, and contacts of infants younger than 6 months.
7. Healthcare personnel.

There are three formulations of influenza vaccine available: inactivated influenza vaccine (IIV), live-attenuated influenza vaccine (LAIV), and recombinant influenza vaccine (RIV).[43]The vaccines differ in the number of antigens that they contain, the route of administration, and antigen presentation.

Traditionally, influenza vaccines, both inactivated and live attenuated, have contained three influenza strains, two influenza A and one influenza B strain. The 2013 to 2014 influenza season will be the first time a quadrivalent vaccine will be available. The quadrivalent influenza vaccines contain an additional influenza B virus strain.

The IIV can be trivalent or quadrivalent, and all are injectable. Most formulations are administered intramuscularly except for one that is given as an intradermal injection. The IIV is contraindicated in patients with a severe, anaphylactic allergic reaction to eggs or any vaccine components. A new cell culture-based IIV is available but still contains some egg protein and the same precautions should be taken. In patients with a mild reaction to egg products, for which hives is the only symptom, IIV can be administered by a healthcare provider familiar with egg allergy if the recipient is observed for at least 30 minutes after vaccination. There is also a high dose IIV that is available for people over the age of 65. This vaccine is also a trivalent, inactivated, injectable vaccine that appears to promote a more robust immune response in older adults; the clinical impact is unclear.

The LAIV is an alternative for healthy, nonpregnant patients aged 2 to 49 years. In 2013, the only available LAIV is quadrivalent. It contains live virus that has been altered so that it survives only at the cooler temperatures in the nasal mucosa. It is not licensed for use during pregnancy, but postpartum women are eligible to receive the LAIV. It should be avoided in patients 2 to 4 years of age with a history of reactive airway disease, although the risk the LAIV poses in such patients is unclear. Patients receiving chronic aspirin therapy should not be given the LAIV because to the risk of Reye's syndrome with wild-type virus. Viral shedding of the attenuated virus may occur, at very low levels, for up to 7 days after receipt of the LAIV. Out of an abundance of caution, LAIV is not recommended for care providers, including HCP or family members, who will have close contact with severely immunosuppressed persons (defined as those patients such as stem cell transplant recipients who are so immunosuppressed that they currently require a protective environment) in the 7 days after vaccination.[44,45]LAIV should be avoided in patients with history of any kind of allergic reaction to egg products because of limited available data, even when hives is the only reaction.

The RIV, released in 2013, is a trivalent, intramuscular, alternative for persons aged 18 to 49 years. It differs from IIV and LAIV in that it is composed of three recombinant hemagglutinin (HA) proteins for influenza A and B, rather than live attenuated or inactivated virus. Its recombinant production uses an insect virus expression system and so does not depend upon the use of eggs. It is an alternative for patients with any type of reaction to egg products, in the appropriate age group.

Vaccination with all forms is contraindicated in patients with an anaphylactic allergic reaction to any component of the vaccine. Caution is urged in individuals with a history of Guillain-Barré syndrome (GBS) within 6 weeks following a previous influenza immunization. There is conflicting evidence regarding the risk of GBS following vaccine administration, although most reports have shown no such association.[46]

Because it is impossible to predict when an influenza epidemic will occur in a community, influenza vaccination should be offered in the community as soon as the vaccine becomes available. Vaccine should be offered to everyone >6 months of age, at every encounter during influenza season to increase the chance of immunization. Persons with moderate to severe acute febrile illness usually should not be vaccinated until their symptoms have subsided. However, individuals with minor illnesses (with or without fever) can receive influenza vaccine. In general, inactivated vaccines do not interfere with the immune response to other inactivated vaccines or to live vaccines and can be coadministered.[7]

However, it is prudent to check the annual ACIP influenza vaccination recommendations for any changes

or caveats for that year's vaccine options. Standing orders and reminder systems can increase the rate of immunization in residents of nursing homes and patients who are hospitalized. Programs can also increase the rate of immunization of HCP.[47] See "Healthcare Personnel with Influenza Illness" section in this chapter.

VACCINE SIDE EFFECTS AND COMPLICATIONS

Before vaccination, patients should be informed of the following:

1. The vaccine is formulated annually to protect against influenza strains likely to circulate in the United States in the upcoming winter.
2. IIV contains noninfectious viral components and cannot cause influenza. LAIV can cause nasal congestion, sore throat, and headache for a few days.
3. Respiratory diseases unrelated to influenza vaccination can occur after vaccination.
4. Fever, malaise, myalgia, and other systemic symptoms can occur after vaccination, especially in persons with no prior exposure to influenza vaccine (e.g., young children). However, in placebo-controlled studies, rates were similar between vaccine and placebo recipients.
5. Influenza vaccine should not be administered to persons known to have anaphylactic hypersensitivity to eggs or other components of the vaccine without first consulting a physician.

In the United States, some formulations of IIV might contain small amounts of thimerosal (a mercury containing compound) as a preservative. Some people have raised concerns about mercury toxicity chiefly among infants and pregnant women. Improvements in the vaccine manufacturing processes have resulted in vaccine batches with no detectable or only very low levels of thimerosal. No evidence of harm caused by thimerosal in vaccines has been reported. Preservative-free influenza vaccine is available. The LAIV contains no thimerosal.

PREVENTION AND CONTROL: ANTIVIRAL CHEMOPROPHYLAXIS

Annual influenza vaccination is the best way to prevent influenza, but antivirals medication are approximately 70 to 90 percent effective in preventing influenza and can be useful adjuncts to vaccination. Routine chemoprophylaxis is not recommended to avoid development of resistance, but there are specific situations and patients that would benefit from chemoprophylaxis.[35] Chemoprophylaxis with antivirals is recommended when there is a respiratory outbreak of influenza among high-risk persons in institutional settings (e.g., nursing homes). All exposed or at-risk residents, as well as unvaccinated personnel, should receive at least 2 weeks of antiviral therapy. Antivirals should be continued for at least 1 week after the last known case was identified with a minimum of 2 weeks of total treatment. Unvaccinated HCP only require 2 weeks of treatment after receiving the vaccine. Other scenarios in which antivirals can be considered include postexposure prophylaxis in patients or HCP at high risk of complications from influenza who are not able to receive the vaccine.

HEALTHCARE PERSONNEL WITH INFLUENZA ILLNESS

All HCP who develop signs and symptoms of an upper respiratory infection should be restricted from patient care activities until they have recovered. HCP who develop lab-confirmed influenza should be instructed to immediately stop patient care activities, don a facemask until they are away from patient care areas and other personnel, and notify their supervisors and infection prevention personnel. They should be excluded from work for 5 days or for at least 24 hours after they no longer have a fever, whichever is longer. If cough and sneezing are still present upon return to work, then adherence to respiratory hygiene, cough etiquette, and frequent hand hygiene should be reinforced. If the HCP cares

for patients in a protective environment (e.g., hematopoietic stem cell transplant patients), temporary reassignment or exclusion from work should be considered until completely asymptomatic to avoid exposing high-risk patients.

INFLUENZA VACCINATION CONSIDERATIONS: HEALTHCARE PERSONNEL

The CDC has recommended influenza vaccination of HCP since 1984. Despite the known benefits of vaccination, rates show that only 72 percent of HCP were vaccinated during the 2012 to 2013 influenza season.[48]Recent data confirm that HCP vaccination can result in decreased mortality among nursing home residents. Regulatory agencies are increasing requirements that healthcare facilities offer free vaccinations, with education and incentives to increase compliance rates, as well as encouraging public reporting of facility HCP influenza vaccination rates. The CDC's Healthy People 2020 campaign has set an HCP vaccination rate of 90 percent as the target.

A comprehensive influenza infection prevention plan includes early identification and isolation of patients, annual education about influenza and the benefits of vaccination for HCP and patients, restricting ill patients and HCP, and hand hygiene as well as vaccination of HCP. Healthcare facilities must evaluate HCP influenza vaccination rates annually and use the data to implement improvement plans and tools aimed at increasing vaccination rates every year.[49]Voluntary vaccination program strategies with requirements for nonimmune HCP (e.g., wearing a mask, area reassignment) have successfully increased vaccination rates, but programs making influenza vaccination a condition for employment have shown the greatest success.[47,50,51]

INFLUENZA INFECTION PREVENTION MEASURES IN HEALTHCARE SETTINGS

Influenza is spread from person to person primarily by deposition of large droplets, droplet nuclei, or aerosols onto the mucosal surfaces of the upper or lower respiratory tract of a susceptible person during close contact with an infected person. The primary mode of transmission appears to be through large droplets. The extent of transmission by hands or fomites is unknown, but it is not considered to be a primary mode of transmission. During the 2009 H1N1 influenza pandemic, there were multiple reports of healthcare-associated outbreaks.[52,53]There have also been reports of healthcare-associated transmission of influenza from previously vaccinated inpatients,[54]and of healthcare-associted transmission of influenza in nonepidemic time periods.[55]The fundamental elements to prevent influenza transmission as defined by the CDC are presented in Table 82-1.

Droplet Precautions

Patients with influenza infection should be in private rooms on Droplet Precautions for 7 days after diagnosis or 24 hours after the resolution of fever and respiratory symptoms, whichever is longer.[56]

Droplet Precautions may be maintained for longer duration in children and immunocompromised patients who may shed virus longer. Everyone entering the patient's room should wear an isolation or surgical mask. HCP and visitors should discard the mask when exiting the patient's room, and practice good hand hygiene after removing personal protective equipment (PPE).

If the patient must leave his or her room for testing, he or she should wear a barrier mask. If the patient cannot tolerate a mask, the HCP transporting the patient must assist the patient in complying with good respiratory etiquette (see Chapters 28 Standard Precautions, and 29 Isolation Precautions). If

sufficient private rooms are unavailable, room sharing with high-risk patients should be avoided and adequate spatial separation between patients should be maintained. It may be wise to postpone elective surgery in affected patients.

Table 82-1. Fundamental Elements to Prevent Influenza Transmission[56]

Table 82-1 Fundamental Elements to Prevent Influenza Transmission

- Administration of influenza vaccine
- Implementation of respiratory hygiene and cough etiquette
- Appropriate management of ill healthcare personnel
- Adherence to infection control precautions for all patient care activities and aerosol-generating procedures
- Implementing environmental and engineering infection control measures

Airborne Precautions

Although there are limited data available on influenza transmission related to aerosols, some authorities recommend implementing Airborne Precautions, including the use of N95 mask or respirators during activities with a high likelihood of producing respiratory aerosols, including:

- Aerosol-generating procedures (e.g., endotracheal intubation, nebulizer treatment, and bronchoscopy) performed on patients with confirmed or suspected pandemic influenza.
- Emergency intubation or cardiac pulmonary resuscitation of patient with confirmed or suspected pandemic influenza.

The recommendations state that negative pressure rooms are not routinely required for patients with influenza illness. However, airborne infection isolation rooms should be used when performing high-risk aerosol-generating procedures. If workflow, timing, resources, availability, or other factors prevent the use of airborne infection isolation rooms, these activities should be done in a private room (with the door closed) or other enclosed area. Staff in the room should be limited to the minimum number of essential personnel and all should wear respirators.

CONTROL OF INFLUENZA OUTBREAKS IN HEALTHCARE SETTINGS

For suspected influenza outbreaks in institutions, testing of respiratory specimens from patients with suspected influenza should be performed as early as possible.[56]If RIDTs are used in this setting,

negative results should be confirmed by RT-PCR testing. An investigation should be prompted when two or more persons inside a closed setting (e.g., school, nursing facility, hospital) develop clinical signs and symptoms compatible with influenza virus infection within 2 to 3 days of each other. If individuals at high risk of influenza complications reside in that setting, then empiric control measures should be considered.

During an influenza outbreak in a healthcare setting, the following measures should be taken to protect patients and HCP and to reduce the risk of healthcare-associated influenza transmission:

- Perform rapid influenza virus or PCR testing of patients and personnel with recent onset of symptoms suggestive of influenza. While rapid antigen testing is helpful for confirming influenza infection, it should not be relied upon to exclude the diagnosis.
- If possible, obtain viral cultures or RT-PCR from a subset of patients so that the virus type and subtype can be determined (may need to arrange this with local or state public health laboratories).
- Implement Droplet Precautions for all patients with suspected or confirmed influenza.

- Separate suspected and confirmed influenza patients from asymptomatic patients.
- Restrict personnel movement from areas of the facility having outbreaks.
- Immunize unvaccinated patients and HCP with currently recommended influenza vaccine.
- Administer influenza antiviral chemoprophylaxis and treatment to nonimmune patients and health HCP according to current recommendations.
- Consider antiviral chemoprophylaxis for all HCP, regardless of their vaccination status, if the health department determines the outbreak is caused by a variant of influenza virus that is a suboptimal match with the vaccine.
- Limit or stop elective medical and surgical admissions.
- Restrict cardiovascular and pulmonary surgery to emergency cases during influenza outbreaks, especially those characterized by high attack rates and severe illness, in the community or acute care facility.

SPECIAL CONSIDERATIONS: PREGNANT WOMEN AND INFANTS

Pregnant women and small infants are at increased risk of hospitalization from influenza complications. Pregnant women with confirmed or suspected influenza are recommended to receive antiviral treatment with oseltamivir or zanamivir. Pregnancy should not be considered a contraindication for treatment. Neuraminidase inhibitors are "Pregnancy Category C" medications, and although a few adverse events have been reported in animal studies, no causal relation has been established. On the other hand, benefit from treatment has been demonstrated and treatment should start early. Oseltamivir is the preferred choice of treatment in pregnancy. See Table 82-2 for recommendations for preventing influenza transmission between hospitalized infected mothers and their infants.[57]

Influenza Surveillance In Healthcare Facilities

The annual infection prevention and control risk assessment must include the assessment of influenza risk and a plan for influenza surveillance. Infection prevention surveillance must be able to detect annual seasonal influenza epidemics and will therefore include both laboratory and syndromic surveillance components. The syndromic surveillance component is based on the ability to detect ILI. (For information on the clinical signs and diagnosis of influenza, visit the CDC website. See Supplemental Resources.)

Table 82-2 Guidance for Prevention and Control of Influenza in the Peri- and Postpartum Settings

Pregnant women have been shown to be at increased risk of hospitalization from complications secondary to influenza infection. Infection prevention measures for hospitalized pregnant and recently delivered women and their infants are detailed here. These guidelines were developed for clinicians and public health officials.
Before Delivery • Prior to delivery, hospitalized influenza-infected pregnant women should be placed on Droplet Precautions. • Droplet Precautions should continue for 7 days after illness onset or until 24 hours after the resolution of fever and respiratory symptoms, whichever is longer.
During Delivery • Pregnant women with influenza in the labor and delivery suite should be placed on Droplet Precautions. The pregnant woman does not need to wear a mask during labor and delivery, but all healthcare personnel and family in the room should wear a mask. • All persons in the delivery room should practice hand hygiene before and after handling the baby.

After Delivery

- Due to the high risk of complications from influenza infection in a neonate, facilities should consider separating the baby from the mother who is ill with suspected or confirmed influenza during the hospital stay.
- A healthy caregiver should perform feedings if possible. Mothers can express their milk if they intend to breastfeed.
- Optimal length of separation has not been established, and will need to be assessed on a case-by-case basis. During the influenza A 2009 (H1N1) pandemic, guidance recommended to continue separation until the mother:
  - Received antiviral treatment >48 hours,
  - Remained afebrile without antipyretics for >24 hours, and
  - Was able to control cough and respiratory secretions.
- If separation is not possible then the following measures should be taken:
  - Place physical barriers between mother and newborn (e.g., curtain).
  - Keep the baby ≥6 feet away for the ill mother.
  - Ensure a healthy adult is present to care for the newborn.
- If no other adult is present, then the mother should wear a surgical/isolation facemask and practice hand hygiene before each contact with the newborn.

Nursery

- Infants without symptoms, born to mothers with suspected or confirmed influenza, can be cared for in the nursery using Standard Precautions and observed closely for symptoms.
- Symptomatic mothers, other family members, and visitors should not enter the nursery.
- A newborn that develops symptoms should be placed on Droplet Precautions.

Visitors

- Visitors that were in contact with the mother prior to hospitalization should be screened for symptoms before being allowed entry to the unit.
- Visitors of influenza-infected mothers and their infants should receive infection prevention education on Droplet Precautions and hand hygiene and should be asked to practice these measures during their hospital visit.

ILI surveillance in a healthcare facility can be linked to emergency department visits, influenza antiviral usage, and absenteeism in HCP. In addition, many state and local health departments collaborate with healthcare facilities, schools and childcare facilities, pharmacies, long-term care facilities, and medical clinics to collect ILI surveillance data. This then becomes another source of ILI surveillance information that can be utilized in the infection prevention influenza surveillance plan. The annual influenza surveillance serves as a test of the ability to detect pandemic influenza in hospitalized patients and staff.[58] Some healthcare facilities may link to a public health syndromic surveillance database and receive real-time notifications that alert the infection preventionist (IP) to an increase in ILI in the community (e.g., Department of Defense Electronic Surveillance System for the Early Notification of Community-Based Epidemics [ESSENCE][59] or the University of Pittsburgh's open source Real-time Outbreak Surveillance [RODS]).

During influenza season, the influenza surveillance for the facility should also include healthcare-associated transmission of seasonal influenza among patients and HCP in the facility. This information can be used to implement interventions to prevent ongoing transmission within the healthcare facility.[60, 61]

The CDC provides a checklist for pandemic influenza preparedness, including surveillance.[62]

Future Trends

Future research activities include vaccine development and vaccine acceptance among general and healthcare populations. In addition, improvements in surveillance and tracking will enable a more rapid response to increasing case rates.

International Perspective

When considering the international impact of influenza, one of the first areas of concern is a pandemic, as most recently experienced in 2009 to 2010. Much work has been done to prepare for pandemics both in the United States and worldwide. Preparedness planning includes elements such as rapid diagnosis, treatment, prophylaxis, rapid vaccine development and distribution, use and availability of appropriate PPE, safety of HCP, as well as social and political implications. International cooperation has been critical to the development of preparedness programs, as influenza does not respect international borders.

APIC TEXT OF INFECTION CONTROL AND EPIDEMIOLOGY

Foodborne Illnesses

Author(s): Ynes Ortega, PhD, MPH
Associate Professor

Center for Food Safety
University of Georgia
Griffin, GA

Published: October 3, 2014

Abstract

According to the U.S. Centers for Disease Control and Prevention, each year foodborne diseases cause an estimated 48 million illnesses every year in the United States. This includes 9.4 million caused by known pathogens.[1]*It is estimated that 55,961 hospitalizations and 1,351 deaths occur annually in the United States from foodborne illnesses, and that 31 major pathogens are primarily responsible.*[2]*Those most affected are very young, elderly, immunocompromised, and underserved (as it relates to racial and ethnic populations) populations. New foodborne diseases are emerging, and increased global travel and trade broaden the opportunities and deepen the risks of contracting and spreading foodborne illness.*

Key Concepts

- Physicians and other healthcare professionals should[2]:
  - Recognize the potential for a foodborne etiology in a patient's illness.
  - Realize that many cases of foodborne illness have gastrointestinal tract symptoms.
  - Obtain stool cultures in appropriate settings and recognize that testing for some specific pathogens (e.g., *Escherichia coli*O157:H7, *Vibrio*species) must be requested.
  - Report suspected cases to appropriate public health officials
  - Talk with patients about ways to prevent foodborne diseases. Preventing foodborne diseases through food safety education is effective when the healthcare professional increases the patient's understanding of the relationship between a specific behavior that may have caused the foodborne illness. The five major control factors for pathogens are personal hygiene, adequate cooking,

avoiding cross-contamination, keeping food at safe temperatures, and avoiding foods from unsafe sources.

- Appreciate that any patient with foodborne illness may represent the sentinel case of a more widespread outbreak.

Background

To provide practical and concise information on the diagnosis, treatment, and reporting of foodborne illnesses, several government agencies and professional associations collaboratively developed *Diagnosis and Management of Foodborne Illnesses: A Primer for Physicians and Other Health Care Professionals*.[2] This primer was developed by the American Medical Association, the American Nurses Association–American Nurse Foundation, the U.S. Centers for Disease Control and Prevention (CDC), the U.S. Food and Drug Administration's Center for Food Safety and Nutrition, and the U.S. Department of Agriculture's Food Safety and Inspection Service. Copies can be downloaded from the website of the CDC (**www.cdc.gov/mmwr/preview/mmwrhtml/rr5304a1.htm**). Updated information on foodborne pathogen surveillance and studies aimed at estimating the number of episodes, hospitalizations, and deaths caused by foodborne etiologies assist with the analysis of food safety policy and interventions.

The primary focus of this chapter is the four summary tables that can be found in the primer. These tables, which are reproduced here, succinctly present the etiology, incubation period, signs, symptoms, and other essential information about bacterial, viral, parasitic, and noninfectious foodborne illnesses.

New information on food safety is constantly emerging. Recommendations and precautions for people and those at high risk are updated whenever new data about preventing foodborne illnesses become available. Physicians and other healthcare professionals need to be aware of and follow the most current information on food safety.

Basic Principles

- Foodborne illness is related to food ingestion. Gastrointestinal (GI) tract symptoms are the most common clinical manifestations of foodborne illness.
- Foodborne illnesses can be caused by microorganisms, marine organisms, fungi (and their related toxins), and chemical contaminants.
- The bacterial agents most often associated with foodborne illness in the United States include *Salmonella*spp. (11 percent), *Clostridium perfringens*(10 percent), and *Campylobacter*spp. (9 percent).
- Viruses are the most common cause of foodborne illness (58 percent), though testing for viral etiologies of diarrheal disease is rare.
- Leading causes of hospitalizations are nontyphoidal *Salmonella*spp. (35 percent), norovirus (26 percent), *Campylobacter*spp. (15 percent), and *Toxoplasma gondii*(8 percent).[3]
- Leading causes of death are nontyphoidal *Salmonella*spp. (28 percent), *T. gondii*(24 percent), *Listeria monocytogenes*(19 percent), and norovirus (11 percent).[3]
- Requirements for reporting diseases and conditions are mandated by state and territorial laws and/or regulations, but physicians and infection preventionists are encouraged to report all foodborne illness they encounter in an effort to recognize and promote an early response to an outbreak. Some factors to explore to determine the etiology of potential foodborne illness include the incubation period,

duration of the resultant illness, predominant clinical symptoms, and the population involved in the outbreak.

Foodborne Illness

BACTERIAL AGENTS

See Table 83-1.

VIRAL AGENTS

See Table 83-2.

PARASITIC AGENTS

See Table 83-3.

NONINFECTIOUS AGENTS

See Table 83-4.

Table 83-1 . Foodborne Illnesses (Bacterial)

Etiology	Incubation Period	Signs and Symptoms	Duration of Illness	Associated Foods	Laboratory Testing
Bacillus anthracis	2 d to weeks	Nausea, vomiting, malaise, bloody diarrhea, acute abdominal pain	Weeks	Insufficiently cooked contaminated meat	Blood
Bacillus cereus (diarrheal toxin)	8–16 hr	Abdominal cramps, watery diarrhea, nausea	24–48 hr	Meats, stews, gravies, vanilla sauce, vegetables, milk products	Testing not necessary, self-limiting (consider testing food and stool for toxin in outbreaks)
Bacillus cereus (preformed enterotoxin)	1–6 hr	Sudden onset of severe nausea and vomiting; diarrhea may be present	24 hr	Improperly refrigerated cooked and fried rice, meats, pasta, pastry, noodles	Normally a clinical diagnosis. Clinical laboratories do not routinely identify this organism. If indicated, send stool and food specimens to reference laboratory for culture and toxin identification
Brucella abortus, B. melitensis, and*B. suis*	7–21 d	Fever, chills, sweating, weakness, headache, muscle and joint pain, diarrhea, bloody stools during acute phase	Weeks	Raw milk, goat cheese made from unpasteurized milk, contaminated meats	Blood culture and positive serology

Campylobacter jejuni	2–5 d	Diarrhea, cramps, fever and vomiting; diarrhea may be bloody	2–10 d	Raw and undercooked poultry, unpasteurized milk, contaminated water	Routine stool culture; Campylobacter require special media and incubation at 42°(to grow.
Clostridium botulinum—children and adults (preformed toxin)	12–72 hr	Vomiting, diarrhea, blurred vision, diplopia, dysphagia, and descending muscle weakness	Variable (from days to months). Can be complicated by respiratory failure and death.	Home-canned foods with a low acid content, improperly canned commercial foods, home-canned or fermented fish, herb-infused oils, baked potatoes in aluminum foil, cheese sauce, bottled garlic, foods held warm for extended periods of time (e.g., in a warm oven)	Stool, serum, and fooc can be tested for toxir Stool and food can als be cultured for the organism. The tests ca be performed at some state health departmer laboratories and the CDC.
Clostridium botulinum—infants	3–30 d	In infants younger than 12 months, lethargy, weakness, poor feeding, constipation, hypotonia, poor head control, poor gag and sucking reflex	Variable	Honey, home-canned vegetables and fruits, corn syrup	Stool, serum, and fooc can be tested for toxir Stool and food can als be cultured for the organism. The tests ca be performed at some state health departmer laboratories and the CDC.
Clostridium perfringens toxin	8–16 hr	Watery diarrhea, nausea, abdominal cramps; fever is rare	24–48 hr	Meats, poultry, gravy, dried or precooked foods, time- and/or temperature-abused food	Stools can be tested fc enterotoxin and cultur for organism. Because *Clostridium perfringens*can normall be found in stool, quantitative cultures ca be done.
Enterohemorrhagic*Escherichia coli* (EHEC), including *E. coli* O157:H7 and other Shiga toxin-producing*E. coli* (STEC)	1–8 d	Severe diarrhea that is often bloody, abdominal pain, and vomiting. Usually, little or no fever is present. More common in children younger than 4 years.	5–10 d	Undercooked beef, especially hamburger, unpasteurized milk and juice, raw fruits and vegetables (e.g., sprouts), salami (rarely), and contaminated water	Stool culture; *E. coli*0157:H7 requires special media to grow. *E. coli*O157:H7 is suspected, specific testing must be requested. Shiga toxin testing may be done using commercial kits; positive isolates should be forwarded to public health laboratories for confirmation and serotyping.

Enterotoxigenic*E. coli*(ETEC)	1–3 d	Watery diarrhea, abdominal cramps, some vomiting	3–7 d	Water or food contaminated with human feces	Stool culture. ETEC requires special laboratory techniques identification. If suspected, must reque specific testing.
Cronobacter sakazakii	Infants within a few days	In premature babies and babies younger than 1 year old: Fever, poor feeding, irritability, jaundice, seizures. Some babies develop meningitis, necrotizing enterocolitis, sepsis. Death rate is 10 to 80 percent in infants younger than 2 months old. Can be serious in the elderly or immunocompromised	Among survivors 2–8 weeks	Powdered baby formula, powdered milk, herbal teas, starches. Person to person	Laboratory culture
Listeria monocytogenes	9–48 hr for gastrointestinal symptoms, 2–6 wk for invasive disease At birth and infancy	Fever, muscle aches, and nausea or diarrhea. Pregnant women may have mild flulike illness, and infection can lead to premature delivery or stillbirth. Elderly or immunocompromised patients may have bacteremia or meningitis. Infants infected from a mother at risk for sepsis or meningitis.	Variable	Fresh soft cheeses, unpasteurized or inadequately pasteurized milk, ready-to-eat deli meats, hot dogs	Blood or cerebrospinal fluid (CSF) cultures. Asymptomatic fecal carriage occurs; therefore, stool culture usually not helpful. Antibody to listeriolysi may be helpful to identify outbreak retrospectively.
Salmonella spp.	1–3 d	Diarrhea, fever, abdominal cramps, vomiting. *S. typhi*and *S. paratyphi*produce typhoid with insidious onset characterized by fever, headache, constipation, malaise, chills, and myalgia; diarrhea is uncommon, and vomiting is usually not severe.	4–7 d	Contaminated eggs, poultry, unpasteurized milk or juice, cheese, contaminated raw fruits and vegetables (alfalfa sprouts, melons). *S. typhi*epidemics are often related to fecal contamination of water supplies or street-vended foods.	Routine stool cultures

Shigella spp.	24–48 hr	Uncommon cause of foodborne illness and vomiting is usually not severe. Abdominal cramps, fever, and diarrhea. Stools may contain blood and mucus.	4–7 d	Food or water contaminated with human fecal material. Usually person-to-person spread, fecal-oral transmission. Ready-to-eat foods (e.g., raw vegetables, salads, sandwiches) touched by infected food workers.	Routine stool cultures
Staphylococcus aureus (performed enterotoxin)	1–6 hr	Sudden onset of severe nausea and vomiting. Abdominal cramps. Diarrhea and fever may be present.	24–48 hr	Unrefrigerated or improperly refrigerated meats, potato and egg salads, cream pastries.	Normally a clinical diagnosis. Stool, vomit and food can be teste for toxin and cultured indicated.
Vibrio cholerae (toxin)	24–72 hr	Profuse watery diarrhea and vomiting, which can lead to severe dehydration and death within hours.	3–7 d, causes life-threatening dehydration.	Contaminated water, fish, shellfish, street-vendor food; typically from Latin America or Asia.	Stool culture; *V. cholerae*requires speci media to grow. If *V. cholerae*is suspected, specific testing must b requested.
Vibrio parahaemolyticus	2–48 hr	Watery diarrhea, abdominal cramps, nausea, vomiting	2–5 d	Undercooked or raw seafood, such as fish, shellfish	Stool cultures. *V. parahaemolyticus*requi special media to grow. *V. vulnificus*is suspecte specific testing must b requested.
Vibrio vulnificus	1–7 d	Vomiting, diarrhea, abdominal pain, bacteremia, and wound infections. Most common in immunocompromised persons or in patients with chronic liver disease (presenting with bullous skin lesions). Can be fatal in patients with liver disease and immunocompromised persons.	2–8 d	Undercooked or raw shellfish, especially oysters; other contaminated seafood, and open wounds exposed to seawater.	Stool, wound, or bloo cultures. *V. vulnificus*requires spec media to grow. If *V. vulnificus*is suspected, specific testing must b requested.

Yersinia enterocolitica and *Y. pseudotuberculosis*	24–48 hr	Appendicitis-like symptoms (diarrhea and vomiting, fever, and abdominal pain) occur primarily in older children and young adults. May develop erythema nodosum with *Y. pseudotuberculosis*.	1–3 wk, usually self-limiting	Undercooked pork, unpasteurized milk, tofu, contaminated water. Infection has occurred in infants whose caregivers handled chitterlings.	Stool, vomitus, or bloc culture. *Yersinia* require special media to grow. *Yersinia* is suspected, specific testing must b requested. Serology is available in research a reference laboratories.

Table 83-2 Foodborne Illnesses (Viral)

Etiology	Incubation Period	Signs and Symptoms	Duration of Illness	Associated Foods	Laboratory Testing	Treatment
Hepatitis A	28 d average (15–50 d)	Diarrhea, dark urine, jaundice, and flulike symptoms (i.e., fever, headache, nausea, and abdominal pain).	Variable, 2 wk–3 mo	Shellfish harvested from contaminated waters, raw produce, contaminated drinking water, undercooked foods, and cooked foods that are not reheated after contact with infected food handler.	Increase in alanine transaminase (ALT), bilirubin. Positive immunoglobulin M (IgM) and antihepatitis A antibodies.	Supportive care. Prevention with immunization.
Hepatitis E	15–60 days	Fever, fatigue, loss of appetite, nausea, vomiting, abdominal pain, jaundice, dark urine, clay-colored stools, joint pain.	Infectious up to 14 days after onset of jaundice.	Contaminated water or foods. Uncooked/ undercooked pork or deer meat. Shellfish.	Testing for Hepatitis E virus (HEV) or HEV RNA. Considered in persons returning from HEV-endemic regions and seronegative for Hepatitis A, B, C, or other hepatotropic viruses.	Supportive care. No FDA-approved vaccine available in the United States.
Noroviruses (and other caliciviruses)	12–48 hr	Nausea, vomiting, abdominal cramping, diarrhea, fever, myalgia, and some headache. Diarrhea is more prevalent in adults, and vomiting is more prevalent in children.	12–60 hr	Shellfish, fecally contaminated foods, ready-to-eat foods (salads, sandwiches, ice, cookies, fruit) touched by infected food workers.	Routine reverse transcriptase polymerase chain reaction (RT-PCR) and electron microscopy (EM) on fresh unpreserved stool samples. Clinical diagnosis, negative bacterial cultures. Stool is negative for white blood cells (WBCs).	Supportive care such as rehydration. Good hygiene.

Rotavirus	1–3 d	Vomiting, watery diarrhea, low-grade fever. Temporary lactose intolerance may occur. Infants, children, and elderly and immunocompromised persons are especially vulnerable.	4–8 d	Foods contaminated with feces. Ready-to-eat foods (salads, fruit) touched by infected food workers.	Identification of virus in stool via immunoassay.	Supportive care. Severe diarrhea may require fluid and electrolyte replacement. Vaccine currently available for infants
Other viral agents (astroviruses, adenoviruses, parvoviruses)	10–70 hr	Nausea, vomiting, diarrhea, malaise, abdominal pain, headache, fever.	2–9 d	Foods contaminated with feces. Ready-to-eat foods touched by infected food workers. Some shellfish.	Identification of the virus in early acute stool samples. Serology. Commercial enzyme-linked immunosorbent assay (ELISA) kits are now available for adenoviruses and astroviruses.	Supportive care, usually mild, self-limiting. Good hygiene.

Table 83-3 Foodborne Illnesses (Parasitic)

Etiology	Incubation Period	Signs and Symptoms	Duration of Illness	Associated Foods	Laboratory Testing	Treatment
Angiostrongylus cantonensis	1 wk–1 mo	Severe headaches, nausea, vomiting, neck stiffness, paresthesias, hyperesthesias, seizures, and other neurologic abnormalities.	Several weeks to several months.	Raw or undercooked intermediate hosts (e.g., snails or slugs), infected paratenic (transport) hosts (e.g., crabs, freshwater shrimp), fresh produce contaminated with intermediate or transport hosts.	Examination of CSF for elevated pressure, proteins, leukocytes, and eosinophils; serologic testing using ELISA to detect antibodies to *A. cantonensis*.	Supportive care. Repeat lumbar punctures and corticosteroid therapy may be used for more severely ill patients.
Anisakis simplex	24h–2wk	Invasive anisakiasis: severe stomach and abdominal pain, nausea, vomiting, diarrhea. Some develop a strong allergic reaction	Weeks to months	Ocean fish and cephalopods. Cod, haddock, fluke, Pacific salmon, herring, flounder, monkfish, squid	History of consumption of raw ocean fish, endoscopy, radiography, surgery	Removal of worm from body by endoscopy or surgery

Cryptosporidium spp.	2–10 d	Diarrhea (usually watery), stomach cramps, upset stomach, slight fever.	May be remitting and relapsing over weeks to months.	Any undercooked food or food contaminated by an ill food handler after cooking; drinking water.	Request specific examination of the stool for *Cryptosporidium*. May need to examine water or food.	Supportive care, self-limited. If severe, consider paromomycin for 7 days. For children aged 1 to 11 years, consider nitazoxanide for 3 days.
Cyclospora cayetanensis	1–14 d, usually at least 1 wk	Diarrhea (usually watery), loss of appetite, substantial loss of weight, stomach cramps, nausea, vomiting, fatigue.	May be remitting and relapsing over weeks to months.	Various types of fresh produce (imported berries, lettuce, herbs), water.	Request specific examination of the stool for *Cyclospora*. May need to examine water or food.	TMP-SMX for 7 d
Giardia lamblia	1–2 weeks	Malodorous diarrhea, malaise, abdominal pain, flatulence, weight loss. Prolonged infections in children may result in stunted growth and development.	2–6 weeks. May persist for months.	Contaminated water or fresh food. Person to person.	Ova and parasite examination. Commercial direct fluorescence antibody test kits, ELISA.	Metronidazole
Entamoeba histolytica	2–3 d to 1–4 wk	Diarrhea (often bloody), frequent bowel movements, lower abdominal pain.	May be protracted (several weeks to several months).	Any uncooked food or food contaminated by an ill food handler after cooking; drinking water.	Examination of stool for cysts and parasites; may need at least three samples.	Metronidazole
Tenia solium (teniasis)	2–4 months	Usually asymptomatic, nausea, diarrhea, abdominal pain, general malaise. Complications may result in autoinfection and development of cysticercosis.	Years	Insufficiently cooked pork.	Ova and parasite examination. Fecal ELISA test. Examination of expelled proglotids and/or scolex.	Antihelminthic drugs praziquantel or niclosamide
Tenia solium (cysticercosis)	2 months to years	Can be asymptomatic, depends on localization of cyst. Neurocysticercosis presents with seizures, headache, altered mental status, increased intracranial pressure.	Months–years	Contaminated water, foods, or hands during food preparation.	If in eye by ophthalmoscope, if in brain, computed tomography (CT) or serology.	Antiinflamatory and antihelminthic drugs. Treatment should be carefully monitored by experts on matter. Surgery may be needed.

Toxoplasma gondii *Toxoplasma gondii* (congenital infection)	5–23 d In infants at birth	Generally asymptomatic; 20 percent may develop cervical lymphadenopathy and/or a flulike illness. In immunocompromised patients, central nervous system (CNS) disease, myocarditis, or pneumonitis is often seen. Treatment of the mother may reduce severity and/or incidence of congenital infection. Most infected infants have few symptoms at birth. Later, they generally develop signs of congenital toxoplasmosis (mental retardation, severely impaired eyesight, cerebral palsy, seizures) unless the infection is treated.	Months	Accidental ingestion of contaminated substances (e.g., soil contaminated with cat feces on fruit and vegetables), raw or partly cooked meat (especially pork, lamb, or venison). Passed from mother (who acquired acute infection during pregnancy) to child.	Isolation of parasites from blood or other body fluids; observation of parasites in patient specimens via microscopy or histology. Detection of organisms is rare; serology (reference laboratory needed) can be a useful adjunct in diagnosing toxoplasmosis. However, IgM antibodies may persist for 6 to 18 months and thus may not necessarily indicate recent infection. PCR of bodily fluids. For congenital infection, isolation of *T. gondii*from the placenta, umbilical cord, or infant blood. PCR of white blood cells, CSF, or amniotic fluid, or IgM and IgA serology performed by a reference laboratory.	Asymptomatic healthy, but infected, persons do not require treatment. Spiramycin or pyrimethamine plus sulfadiazine may be used for pregnant women. Pyrimethamine plus sulfadiazine (with or without steroids) may be given for ocular disease when indicated. Folic acid is given with pyrimethamine plus sulfadiazine therapy to counteract bone marrow suppression.
Trichinella spiralis	1–2 d for initial symptoms, others begin 2–8 wk after infection.	Acute: nausea, diarrhea vomiting, fatigue, fever, abdominal discomfort followed by muscle soreness, weakness, and occasional cardiac and neurologic complications.	Months	Raw or undercooked contaminated meat, usually pork or wild game meat (e.g., bear or moose).	Positive serology or demonstration of larvae via muscle biopsy. Increase in eosinophils.	Supportive care plus mebendazole or albendazole.

Table 83-4 Foodborne Illnesses (Noninfectious)

Etiology	Incubation Period	Signs and Symptoms	Duration of Illness	Associated Foods	Laboratory Testing	Treatment
Aflatoxins	Cumulative effect	Hemorrhage, jaundice, premature cell death, tissue necrosis of the liver. Edema of lower extremities, abdominal pain, vomiting. Chronic exposure may lead to hepatocellular carcinoma.	Not described	Corn, sorghum, rice, cottonseed, peanuts, tree nuts, cocoa beans, nutmeg.	Presence of aflatoxins in blood, milk, urine.	Supportive care

Antimony	5 min–8 hr usually <1 hr	Vomiting, metallic taste	Usually self-limited	Metallic container	Identification of metal in beverage or food	Supportive care
Arsenic	Few hours	Vomiting, colic, diarrhea	Several days	Contaminated foods	Urine; may cause eosinophilia	Gastric lavage, broncheoalveolar lavage
Cadmium	5 min–8 hr usually less than 1 hr	Nausea, vomiting, myalgia, increase in salivation, stomach pain	Usually self-limited	Seafood, oysters, clams, lobster, grains, peanuts	Identification of metal in food	Supportive care
Ciguatera fish poisoning (ciguatera toxin)	2–6 hr 3 hr 2–5 d	*GI*: abdominal pain, nausea, vomiting, diarrhea *Neurological*: paresthesias, reversal of hot or cold, pain, weakness *Cardiovascular*: bradycardia, hypotension, increase in T-wave abnormalities.	Days to weeks to months	A variety of large reef fish; grouper, red snapper, amberjack, and barracuda (most common).	Radioassay for toxin in fish or a constant history.	Supportive care, IV mannitol. Children more vulnerable.
Copper	5 min–8 hr usually less than 1 hr	Nausea, vomiting, blue or green vomitus	Usually self-limited	Metallic container	Identification of metal in beverage or food	Supportive care
Mercury	1 wk or longer	Numbness, weakness of legs, spastic paralysis, impaired vision, blindness, coma. Pregnant women and the developing fetus are especially vulnerable.	May be protracted	Fish exposed to organic mercury, grain treated with mercury fungicides.	Analysis of blood, hair	Supportive care
Mushroom toxins, short-acting (muscinol, muscarine, psilocybin, coprius artemetaris, ibotenic acid)	<2 hr	Vomiting, diarrhea, confusion, visual disturbance, salivation, diaphoresis, hallucinations, disulfiram-like reaction, confusion, visual disturbance.	Self-limited	Wild mushrooms (cooking may not destroy these toxins)	Typical syndrome and mushroom identified or demonstration of the toxin.	Supportive care
Mushroom toxin, long-acting (amanitin)	4–8 hr diarrhea; 24–48 hr liver failure	Diarrhea, abdominal cramps, leading to hepatic and renal failure.	Often fatal	Mushrooms	Typical syndrome and mushroom identified and/or demonstration of the toxin.	Supportive care; life-threatening, may need life support.

Nitrite poisoning	1–2 hr	Nausea, vomiting, cyanosis, headache, dizziness, weakness, loss of consciousness, chocolate-brown colored blood.	Usually self-limiting	Cured meats, any contaminated foods, spinach exposed to excessive nitrification.	Analysis of the food, blood	Supportive care, methylene blue
Pesticides (organophosphates or carbamates)	Few minutes to few hours	Nausea, vomiting, abdominal cramps, diarrhea, headache, nervousness, blurred vision, twitching, convulsions, salivation, can progress to paralysis and respiratory arrest.	Usually self-limited	Any contaminated foods	Analysis of the food, blood	Atropine; 2-PAM (Pralidoxime) is used when atropine is not able to control symptoms and is rarely necessary in carbamate poisoning.
Puffer fish (tetrodotoxin)	Less than 30 min	Paresthesias, vomiting, diarrhea, abdominal pain, ascending paralysis, respiratory failure.	Death usually in 4–6 hr.	Puffer fish	Detection of tetrodotoxin in fish.	Life-threatening, may need respiratory support.
Scombroid (histamine)	1 min–3 hr	Flushing, rash, burning sensation of skin, mouth and throat, dizziness, urticaria, paresthesias.	3–6 hr	Fish: bluefin tuna, skipjack, mackerel, martin, escolar, and mahi-mahi.	Demonstration of histamine in food or clinical diagnosis.	Supportive care
Shellfish toxins (diarrheic, neurotoxic, amnesic)	Diarrhea shellfish poisoning (DSP), 30 min–2 hr Neurotoxic shellfish poisoning (NSP), few minutes to hours Amnesic shellfish poisoning (ASP), 24–48 hr	Nausea, vomiting, diarrhea, and abdominal pain accompanied by chills, headache, and fever. Tingling and numbness of lips, tongue, and throat; muscular aches; dizziness; reversal of the sensations of hot and cold; diarrhea; and vomiting. Vomiting, diarrhea, abdominal pain, and neurological problems, such as confusion, memory loss, disorientation, seizure, coma.	Hours to 2–3 d	A variety of shellfish, primarily mussels, oysters, scallops, and shellfish from the Florida coast and the Gulf of Mexico. Toxins are produced by microscopic algae (dinoflagelates, algae), and cyanobacteria and accumulated by shellfish.	Detection of the toxin in shellfish; high-pressure liquid chromatography.	Supportive care, generally self-limiting. Elderly persons are especially sensitive to ASP.

Shellfish toxins (paralytic shellfish poisoning)	30 min–3 hr	Diarrhea, nausea, vomiting leading to paresthesias of mouth, lips; weakness, dysphasia, dysphonia, respiratory paralysis.	Days	Scallops, mussels, clams, cockles. Toxins are produced by microscopic algae (dinoflagelates, algae), and cyanobacteria and accumulated by shellfish.	Detection of toxin in food or water where fish are located; high-pressure liquid chromatography.	Life-threatening, may need respiratory support.
Sodium fluoride	Few minutes–2 hr	Salty or soapy taste, numbness of mouth, vomiting, diarrhea, dilated pupils, spasms, pallor, shock, collapse.	Usually self-limited	Dry foods (such as dry milk, flour, baking powder, cake mixes) contaminated with sodium fluoride-containing insecticides and rodenticides.	Testing of vomitus or gastric washings; analysis of the food.	Supportive care
Thallium	Few hours	Nausea, vomiting, diarrhea, painful paresthesias, motor polyneuropathy, hair loss.	Several days	Contaminated food	Urine, hair	Supportive care
Tin	5 min–8 hr. usually less than 1 hr	Nausea, vomiting, diarrhea	Usually self-limited	Metallic container	Analysis of the food	Supportive care
Vomitoxin	Few minutes to 3 hr	Nausea, headache, abdominal pain, vomiting	Usually self-limited	Grains such as wheat, corn, barley	Analysis of the food	Supportive care
Zinc	Few hours	Stomach cramps, nausea, vomiting, diarrhea, myalgia.	Usually self-limited	Metallic container	Analysis of the food, blood and feces, saliva or urine.	Supportive care

PRIONS AND TRANSMISSIBLE SPONGIFORM ENCEPHALOPATHIES

Prions are proteins that under normal physiologic conditions are found on a variety of cells, particularly in the nervous tissue. The disease develops when normal prions come into contact with disease-causing prions. These proteins are misfolded and can induce other normally folded proteins to misfold and cause variant Creutzfeldt-Jakob disease (vCJD). It can be acquired by ingestion of diseased cattle meat. Symptoms appear after about 10 years and include depression, psychiatric problems, and neurologic symptoms that can lead to death. Disease can last from months to years. Diagnosis of vCJD is based on patient history and clinical symptoms. Supportive therapy is recommended.

Conclusions

The relationship between the safety of our food supply and the development of illness has become an increasingly important concern for both consumers and healthcare providers. Food that is contaminated with a disease-causing pathogen often looks, smells, and tastes like a safe food product, so connecting the illness with a food is very difficult unless other patients present with the same symptoms. Travel to areas where sanitation is not ideal and consumption of foods prepared without proper cooking practices that may be risk factor for acquiring emerging and exotic diseases not endemic to the place of residence.

In a healthcare setting, the infection preventionist should be actively involved in monitoring and evaluating the operational aspects of food service in an effort to prevent foodborne illness in patients, families, visitors, medical staff, and healthcare facility staff. In addition to this internal monitoring and evaluation, the infection preventionist is responsible for reporting cases of potential foodborne illnesses to the appropriate public health entities. It is therefore important for infection preventionists to report noticeable increases in unusual illnesses, symptom complexes, or disease patterns (even without definitive diagnosis) to public health authorities. Prompt reporting of unusual patterns of diarrheal/GI tract illness, for example, can allow public health officials to initiate an epidemiologic investigation earlier than would be possible if the report was delayed until a definitive etiologic diagnosis was made.

Future Trends

In addition to the information presented in this chapter, emerging infections are becoming increasingly recognized as important aspects of food safety. Examples of avian influenza and its impact on poultry, bovine spongiform encephalopathy and its impact on the beef industry, and the emergence of severe acute respiratory syndrome (SARS) and its epidemiologic links to the open-air markets in some Asian countries demonstrate the relationships among cultures, environments, and food safety. New information on food safety is constantly emerging and should be part of the continuous education process of the infection preventionist. Recommendations and additional information can be obtained through public health information networks such as the CDC and local health departments. Healthcare professionals need to be aware of and follow the most current information on food safety.

International Perspective

Increased opportunities for travel and trade bring increased risks of contracting and spreading a foodborne illness locally, regionally, and even globally. In many parts of the world, the incidence of traditional foodborne illnesses and the emergence of new diseases are the result of shifts in human demographics and food preferences, changes in food production and distribution systems, globalization, microbial adaptation, and strained or inadequate public health systems.

Abstract

Legionella pneumophila*is a common cause of both community-acquired and healthcare-associated pneumonia. Clinical manifestations are nonspecific, but high fever, diarrhea, and hyponatremia are often distinctive. Diagnostic modalities include culture on selective media and urinary antigen detection. Quinolone and macrolide antibiotics are highly effective when initiated early in the course. Endemic hospital-acquired Legionnaires' disease is often underdiagnosed and overlooked. Infection has been linked to drinking water distribution systems of acute care and extended care facilities, with warm water systems typically implicated. Health departments and public agencies have issued infection prevention guidelines aimed at preventing outbreaks in facilities in which Legionnaires' disease has been overlooked. These guidelines include diagnostic testing for* Legionella *infection and culturing of the drinking water distribution system. Superheating and flushing or hyperchlorination of the water distribution are short-term approaches to terminate an outbreak. Long-term systemic water treatment with copper-silver ionization, chlorine dioxide, and monochloramine has also been shown to be effective in controlling* Legionella.*Proactive culturing for* Legionella*of the water distribution system when cases of hospital-associated Legionnaires' disease have not been discovered is an evidence-based method of prevention.*

Key Concepts

- Diagnosis and treatment of Legionnaires' disease
- Proactive surveillance of the environment to assess risk and justify preventive interventions
- Disinfection of water distribution systems

Background

*Legionella pneumophila*was first identified as the infectious agent causing pneumonia among attendees at the 1976 American Legion Convention held at a Philadelphia, Pennsylvania hotel.[1]The first known outbreak of healthcare-associated Legionnaires' disease was retrospectively identified at St. Elizabeth's Hospital, Washington, DC, in 1965. Although epidemics dominated the earlier reports, *L. pneumophila*is now known to be a common cause of sporadic and healthcare-associated pneumonia. The Centers for Disease Control and Prevention (CDC) estimates that less than 5 percent of cases are diagnosed and reported to the CDC.[2]

Based on the National Notifiable Disease Surveillance System (NNDSS) and the Supplemental Legionnaires' Disease Surveillance System, CDC found that confirmed cases from 2000 to 2009 increased 217 percent from 1,110 in 2000 to 3,522 in 2009. The crude national incidence rate increased 192 percent (0.39 to 1.15 per 1,000). In 2009, the NNDSS received over 3,500 case reports, the most since legionellosis became reportable in 1976.

For a case to be considered confirmed by NNDSS, it must be clinically compatible with legionellosis and meet at least one of the confirmatory laboratory criteria: (1) recovery of *Legionella*sp. in culture, (2) detection of *L. pneumophila*serogroup 1 antigen in urine, or (3) a fourfold or greater rise in *L. pneumophila*serogroup 1 antibodies.[3]

Microbiology

The family *Legionellaceae*contains more than 50 species. *Legionella*organisms are aerobic Gram-negative fastidious bacteria that do not grow on standard bacteriologic media; thus, specialized laboratory methods and culture media are necessary for diagnosis. The lack of in-hospital availability of these methods leads to underdiagnosis. *Legionella*species can cause pneumonia (Legionnaires' disease) and Pontiac fever, a flulike illness. Approximately 25 species of *Legionella*have been demonstrated to cause human infection, with the remainder having been isolated from the environment and not linked to human infection.[4]The species most commonly associated with disease is *L. pneumophila*. Although numerous serogroups exist, most infections in healthcare facilities are caused by *L. pneumophila*serogroups 1, 4, and 6. Other species implicated in infections include *L. micdadei, L. bozemanii*, and *L. dumoffii.*These species are also notably underdiagnosed because diagnosis requires the use of respiratory cultures since commonly used urinary antigen test fails to identify these species.

RESERVOIR

The natural habitat for *Legionella*is water; thermally polluted rivers and streams are more likely to harbor *Legionella*. Because the organism is chlorine tolerant, it survives the water treatment processes and passes into the drinking water distribution systems in small numbers. Water distribution systems provide favorable water temperatures (105°F to 120°F [41°C to 49°C]), physical protection within biofilms, and nutrients to promote growth.

Pathogenesis

Pathogenic microorganisms cause pneumonia by entering the lung via aspiration or direct inhalation. Both mechanisms are operative for *Legionella*. Although aerosolization with direct inhalation originally was thought to be the primary mode of transmission, epidemiologic studies now show that aspiration is more common, especially in healthcare-associated cases. This is supported by the consistent association of increased risk of Legionnaires' disease in cigarette smokers, patients with chronic pulmonary disease, and persons who abuse alcohol—conditions predisposing to pneumonias caused by aspiration.[5]

L. pneumophila causes more severe pneumonia than most bacterial pathogens, and patients with Legionnaires' disease are more likely to be admitted to intensive care units than are patients with pneumonia caused by other microbial etiologies.[5] Cell-mediated immunity is the primary host defense mechanism.[6,7,8,9] It has been suggested that the ability of *Legionella* to replicate within protozoa has provided *Legionella* with the capacity to replicate in human alveolar macrophages and monocytes.[10] Once *Legionella* has been internalized into the host cell, a bacterial vacuole associates with mitochondria and the endoplasmic reticulum. The bacteria subverts host cell processes that would normally eliminate an intracellular threat. The type IV secretion and Dot/Icm systems appear to be required for intracellular replication and establishment of the *Legionella*-containing vacuole. *L. pneumophila* also possesses other virulence factors such as lipopolysaccharide, flagella, pili, and outer membrane proteins, exoproteases, and cytotoxins.

Epidemiology

RISK FACTORS

Risk factors for Legionnaires' disease have consistently been found to include advanced age, male gender, cigarette smoking, alcohol abuse, and chronic pulmonary disease. Immunosuppressed hosts are most frequently involved in healthcare acquisition. Solid organ transplant recipients appear to be at highest risk. Other risk factors include corticosteroid usage and renal failure. Infections in patients with acquired immunodeficiency syndrome (AIDS) are relatively uncommon, but when they occur, clinical manifestations may be unusually severe.

Healthcare-associated *Legionella* infection has been reported in immunosuppressed children and in children with underlying pulmonary disease.[11,12,13] A review of the literature for *Legionella* cases in children found that 51 percent were under 2 years of age and 54 percent were healthcare-associated.[13]

An outbreak of 11 cases of Legionnaires' disease was reported in newborn babies in a Cyprus neonatal unit. The mortality rate in this outbreak was 27 percent and the source of *Legionella* bacteria was the water system of the neonatal unit.[14] Legionellosis has also been reported in infants delivered by water birth; aspiration of contaminated water is the presumed mechanism.[15,16]

Legionella ranked as the third most common etiologic agent among all outbreaks associated with drinking water, with two-thirds of the legionellosis outbreaks occurring in healthcare settings.[17] Flooding and

increased rainfall have been suggested as contributing factors.[18,19,20]Seasonality with increased incidence during the summer months has also been reported.[21,22]

COMMUNITY-ACQUIRED PNEUMONIA

Based on a large-scale Ohio study of community-acquired pneumonia, fewer than 10 percent of sporadic community-acquired legionellosis cases are diagnosed.[2]Prospective studies of community-acquired pneumonia (CAP) have shown that *Legionella*ranks in the top four causes of pneumonia. Outbreaks of community-acquired legionellosis infections continue to be linked to hotels, decorative fountains, spa displays, and cruise ships.[1,2,23,24,25]Sporadic community-acquired cases have been linked to dental offices,[3]apartment buildings (especially if residents are elderly),[26,27]and home and workplace water systems.[28,29]

Community-acquired Legionnaires' disease in Europe has increased 12 percent from 2009 to 2010. The German Competence Network of Community-Acquired Pneumonia study group estimated 56,000 to 118,000 cases annually based on the incidence ratio of 180 to 360 cases per one million people.[30]In this CAPNETZ study, *Legionella*pneumonia in ambulatory patients was shown to differ in clinical characteristics and outcome compared to patients requiring hospitalization. Ambulatory patients with *Legionella*pneumonia were younger and had fewer comorbidities and a milder clinical course without fatalities.

The number of reported cases and clinical presentation of Legionnaires' disease varies with age. In the United States between 2000 and 2009, 74 percent of cases were in persons 50 years of age and older.[3]Patients ages 65 and older with CAP caused by *Legionella*have a higher frequency of comorbidity and presented less frequently with fever and laboratory abnormalities of Legionnaires' disease than do younger patients. Consequently, a high index of suspicion and the routine application of urinary antigen detection is critical for diagnosing *Legionella*pneumonia in elderly patients.[31]

HEALTHCARE-ASSOCIATED PNEUMONIA

Since the late 1970s, numerous hospitals and long-term care facilities have reported outbreaks of healthcare-associated Legionnaires' disease.[12,32,33,34,35]Transmission has been consistently linked to the drinking water distribution systems. The incidence of healthcare-associated infection depends on the degree of contamination of the drinking water system with the *Legionella*and the susceptibility of the patient population to infection. The proportion of water distribution system outlets that are positive for *Legionella*(percent distal site positivity) correlates with occurrence of disease, but the density (reported as colony forming units per milliliter [cfu/mL]) of *Legionella*in the water obtained from these distal sites does not.[36,37,38,39,40]Decorative water fountains in healthcare facilities have also been linked to clusters of Legionnaires' disease in patients.[41,42]Unrecognized endemic disease may exist over a prolonged period of time in the absence of active surveillance for cases. Case fatality can be as high as 33 percent for healthcare-acquired Legionnaires' disease compared to 13 percent for community-acquired cases.[43]

There is a growing number of cases of healthcare-associated Legionnaires' disease among the elderly patients and patients in assisted living and long-term care facilities.[27,44,45]Sporadic and outbreak-related

cases occur in this population due to comorbidities, impaired immunity, and propensity for aspiration. Increased incidence of legionellosis in patients in long-term care facilities has followed the increased use of *Legionella*diagnostic testing in this patient population.

MODE OF TRANSMISSION

Aspiration is a major route of transmission, especially in healthcare-associated pneumonia.[46]Intubation, surgery requiring general anesthesia, and nasogastric tubes have been associated with healthcare-associated legionellosis via aspiration.[33,47]Person-to-person transmission does not occur; thus, isolation of these patients is not required. Aerosolization by use of respiratory tract devices (such as humidifiers and nebulizers), aspiration, and instillation directly into the lung during respiratory tract manipulation have all been linked to healthcare-associated infections.[47,48]In addition to drinking water distribution systems of healthcare facilities, *Legionella*may be transmitted from a variety of man-made aquatic devices including evaporative condensers, whirlpool spas, industrial equipment, and decorative fountains.[25]

Despite widespread belief, air conditioners have not been implicated in Legionnaires' disease. The role of cooling towers has also been overestimated.[49]Healthcare-associated Legionnaires' disease attributed to cooling towers has dramatically decreased following the discovery that the organism can colonize the drinking water of hospitals.[32]Although the first environmental isolate was from a showerhead,[50]an epidemiological link between showering and disease has not been convincingly demonstrated.[33,47]One study showed an inverse relationship between showering and healthcare-associated Legionnaires' disease—patients that got Legionnaires' disease were too sick to have showered and aspiration was the presumed mode of transmission.[47]However, a British study reported that Legionnaires' disease was higher among older adults who showered when compared to those who took tub baths.[27]The relative risk (RR) was 7.02 (0.45 to 128.21) for showering versus 0.13 (0.02 to 1.09) for any tub baths.[27]

Clinical Presentation

*Legionella*infection can manifest in the following ways: as asymptomatic seroconversion, as a flulike illness without pneumonia (Pontiac fever), as Legionnaires' disease (pneumonia), or on very rare occasions as extrapulmonary infection.

LEGIONELLA PNEUMONIA(LEGIONNAIRES' DISEASE)

Pneumonia is the most common clinical infection. Laboratory abnormalities are common but nonspecific and include renal and hepatic dysfunction, thrombocytopenia, leukocytosis, and hypophosphatemia. Hyponatremia (serum sodium less than 130 mEq/L) occurs significantly more frequently in Legionnaires' disease than in pneumonias of other etiologies. Hematuria and proteinuria are also common. Serum ferritin levels have also been noted to be elevated in Legionnaires' disease.[5]Elevated procalcitonin levels are a marker for severity of illness.[5]

The incubation period from time of exposure to onset of Legionnaires' disease is typically 2 to 10 days. The infection produces a broad spectrum of symptoms, from mild cough and low-grade fever to rapidly progressive pneumonia, stupor, and multiorgan failure. Chest radiographs usually show a new infiltrate,

which increases in size and density and may progress to multiple lobes. The cough is slightly productive and may be blood-tinged and nonpurulent; pleuritic chest pain is common. Lung abscesses can occur in immunosuppressed hosts. Fever is almost always present, with temperatures often exceeding 40°C (104°F). Nonspecific complaints including malaise, myalgias, anorexia, headache, and confusion are often present. Gastrointestinal tract symptoms are occasionally prominent and include nausea, vomiting, and abdominal pain. Watery diarrhea is seen in 25 to 50 percent of patients.

*Legionella*can disseminate via the blood to extrapulmonary sites. Endocarditis and pericarditis are the most common extrapulmonary infections.[51,52]Two cases of osteomyelitis have been reported.[53]

Myocardial involvement has been reported.[54]Wound infections can occur from contamination of the wound by water colonized with *Legionella*organisms. *L. pneumophila*cellulitis without pneumonia was reported in a 65-year old immunocompromised patient.[55]Unfortunately, extrapulmonary sites are infrequently cultured for *Legionella*(which needs specialized culture media), thus cases may be underreported.

Neurologic symptomatology is common in patients with severe Legionnaires' disease, especially confusion. Problems range from myositis to acute disseminated encephalomyelitis. Hyperintense lesions of the splenium of the corpus callosum were noted in a patient with human immunodeficiency virus (HIV) infection and a diagnosis of *Legionella*pneumonia.[56]

PONTIAC FEVER

*Legionella*infection may also present as an acute self-limiting entity known as Pontiac fever. Onset is usually 24 to 48 hours after exposure and occurs in persons without underlying disease. Pneumonia is not present. Common symptoms include high fever, chills, myalgias, and headache. Recovery occurs within 2 to 5 days without treatment. Healthcare-associated cases have not been reported previously. However, in a survey of 19 retirement homes, 11 Pontiac fever-like episodes occurred over a 4-month period in the nurses, but no cases of *Legionella*were found in patients. Of the cases affecting the nurses, eight complied with the definition of Pontiac fever. Water concentrations of *Legionella*organisms were more than 10,000 cfu/L.[57]Thus far, fatality cases have not been linked to Pontiac fever. Whirlpool spas have also been the source of some outbreaks.[58,59]In one family, four members who used their own private whirlpool spa became ill; one with *Legionella*pneumonia and three with Pontiac fever. The whirlpool spa, garden shower, and garden hose of this household were all positive for *L. pneumophila*serogroup 1.[60]An outbreak of Pontiac fever caused by *L. longbeachae*was linked to aerosolized potting mix.[61]The attack rate reported in Pontiac fever outbreaks has been high (95 percent) compared with the attack rates seen in Legionnaires' disease outbreaks (0.1 percent to 5 percent).[2]

Diagnosis

Clinical awareness is critical for rapid diagnosis and treatment of Legionnaires' disease. Due to nonspecific clinical presentation, it is not possible to predict the presence of *Legionella*infection, and underdiagnosis of Legionnaires' disease is common. This was demonstrated by Hollenback et al., who determined that even when following the Infectious Disease Society of America (IDSA) guidelines for testing for *Legionella*species, 41 percent of *Legionella*cases were missed.[62]The practice guidelines for

the management of community-acquired pneumonia have been criticized for recommending testing for *Legionella*only for patients with "enigmatic" pneumonia.[63]

Testing for *Legionella*species is recommended for all patients with community-acquired pneumonia and requires specialized diagnostic laboratory tests. The definitive test for the diagnosis of Legionnaires' disease is isolation of the organism by culture. The sensitivity in reference laboratories is at least 80 percent. Unlike routine sputum cultures, special conditions are required to recover this slow-growing and fastidious bacteria. In addition, to achieve a high yield from sputa, the specimen must be plated on multiple specialized media that contain antibiotics to suppress normal flora, which may interfere with the organism's growth.[64,65]Other clinical specimens for diagnosis may include lung tissue, pleural fluid, tracheal aspirate, and bronchial washings; concentration of specimens (e.g., by centrifugation) prior to inoculation of media is recommended.[64]Culture specimens are invaluable if an epidemiological link to an environmental source is to be made. Molecular subtyping methods include monoclonal antibody subtyping and pulsed-field gel electrophoresis (PFGE) of bacterial DNA. Sequence-based typing methods are also used, but are available only in reference laboratories.

Unlike many common pneumonia-causing bacteria, *Legionella*organisms are not easily visualized with Gram stain. However, the organism may be detected with the direct fluorescent-antibody (DFA) stain examined under an ultraviolet microscopic for same-day results. There are limited species and serogroups detected with DFA staining, and the sensitivity (range, 25 to 75 percent) is lower than isolation by culture.[64]

The urinary antigen is now the most commonly used test for (Figure 84-1). In a review of Legionnaires' disease cases reported to the CDC from 2005 to 2009, the urine antigen test was used to confirm 97 percent of U.S. resident cases.[3]The urine antigen test also constitutes 73 percent of diagnostic tests for *Legionella*pneumonia in Europe.[30]Although its use has undoubtedly increased the number of cases identified, a disadvantage of this test is the inability to detect serogroups and species other than *L. pneumophila*serogroup 1. The sensitivity of the test is approximately 80 to 90 percent with a specificity of 90 to 100 percent. It should be noted that in some hospitals, the urine antigen test has failed to be positive when the infecting organism is a subtype of *L. pneumophila*serogroup 1 such as Bellingham or OLDA—strains more common in hospitalized patients.[66]The test can remain positive for days even during the administration of antibiotic therapy and for prolonged periods in immunocompromised patients. The urinary antigen testing methods include both enzyme immunoassay (EIA) and immunochromatographic membrane (ICT) assay.[64]The Binax NOW test was the first ICT test, but at least seven other manufacturers now offer a version of this test. It is important to note that the sensitivity and specificity has been variable with some of these tests and both false-positive and false-negative test results have been reported.[67,68]Therefore, a positive antigen test result may rule in *L. pneumophila*serogroup 1, but the rate of false-negative findings should cause the clinician to be cautious about withdrawing anti-*Legionella*therapy.

Figure 84-1.

*Legionella*urinary antigen immunochromatographic (ICT) test showing positive result after insertion of urine-soaked swab and 15-minute incubation. Pink "Sample" line indicates a positive resu

View Image

Serology has become less important with the advent of rapid diagnostic tests and now accounts for less than 1 percent of diagnosed cases. Fourfold seroconversion is required for definitive diagnosis, so both

an acute serology and convalescent serology are required 4 to 12 weeks after onset of illness. Maximal sensitivity requires both immunoglobulin G and immunoglobulin M antibody determination. Polymerase chain reaction (PCR)-based assays for *Legionella*are highly specific but not more sensitive than culture.[69]Use of PCR on respiratory specimens increased the diagnosis of community-acquired Legionnaires' disease due to *L. longbeachae*in New Zealand—an area where *L. longbeachae*is endemic.[70]

In an epidemiologic investigation, both phenotypic and genotypic methods alone, or in combination, can be used. This may be useful to link patient isolates and environmental reservoirs. Pulsed-field gel electrophoresis (PFGE) and methods have been used including serotyping, monoclonal antibody subtyping, isoenzyme analysis, restriction fragment length polymorphism of rRNA (ribotyping) or chromosomal DNA, amplified fragment length polymorphism, repetitive-element PCR, restriction endonuclease (analysis of whole-cell DNA), arbitrarily primed PCR, and 16S-23S spacer analysis. Results linking patient isolates with an environmental source should be interpreted with caution and considered along with epidemiological information.[64]Coordination with local, state, regional, or national health departments is recommended in a suspected outbreak. (See **12. Outbreak Investigations**.)

Treatment

Antibiotic therapy is highly effective if initiated early. Quinolones (levofloxacin, ciprofloxacin) and macrolides (azithromycin, clarithromycin) are the drugs of choice for treatment.[33]Azithromycin or levofloxacin can be considered as first-line treatment. Other antibiotics used successfully include tetracycline, tigecycline, and clarithromycin.[71]Doxycycline has been successfully used, and rifampin has been used in combination with other antibiotics for severe cases, though data is lacking for increased efficacy. Erythromycin is no longer the antibiotic of choice due to side effects. Defervescence usually occurs within 3 to 5 days. Duration of therapy is usually 10 to 14 days; however, longer duration (21 days) may be appropriate for some immunosuppressed patients. The mortality rate for healthcare-associated *Legionella*pneumonia has decreased from 46 percent in 1982 to less than 10 percent with the advent of quinolone therapy.[72]

Prevention And Control Of Healthcare-Associated Legionnaires' Disease

The knowledge that Legionnaires' disease is linked to exposure to the bacteria from the water distribution system of hospitals and other buildings has prompted numerous guidance documents for disease prevention. The first such document was published in 1993 by the Allegheny County Health Department in Pittsburgh, Pennsylvania.[73]This guidance differed from the CDC's in that environmental testing for *Legionella*was to be performed annually without the precondition of identified cases of healthcare-associated cases. The premise of this recommendation was the common misdiagnosis or missed diagnosis of Legionnaires' disease due to the lack of diagnostic testing. Although numerous studies have demonstrated the utility of this approach as a prevention strategy, the role for routine testing of water systems continues to be debated.

In studies in the United States, Italy, France, Taiwan, Spain, Greece, and most European countries, routine culturing of the hospital drinking water for *Legionella*is recommended.[74]Approximately 60 percent of private hospitals and 93 percent of public hospitals in Southeastern Italy were positive for *Legionella*spp. *L. pneumophila*serogroup 1 was the most frequently isolated species. Risk assessment evaluation proved useful in predicting *Legionella*spp. contamination in water systems.[75]

CULTURING THE WATER DISTRIBUTION SYSTEM OF HEALTHCARE FACILITIES

The water distribution system in healthcare facilities has been the source of *Legionella*outbreaks in both acute and chronic care facilities. Consequently, a primary objective of a healthcare facility should be to monitor and maintain the potable water distribution system in such a manner so that *Legionella*will be controlled. When a patient receives a diagnosis of healthcare-associated Legionnaires' disease, culturing of the water sites to which the patient was exposed is indicated.[76]Distal sites include water faucets, ice machines, water used in respiratory tract devices, and any other water source to which the patient is exposed.[1,77]Sites might include water in other units where the patient may have been, such as the radiology department or the physical therapy department. If a link is found between an environmental site and the patient with Legionnaires' disease, expanded surveillance for other cases of healthcare-associated *Legionella*pneumonia should then be undertaken. Particular attention should be focused on areas housing high-risk patients, such as transplant units and intensive care units. If additional cases are found, a system-wide culturing of the water distribution system should be undertaken. Routine environmental culturing should continue; however, the time interval can be expanded if the cultures remain negative and cases cease to be diagnosed. The knowledge that the medical facility's water supply is colonized with *Legionella*should be shared with clinicians. This knowledge will increase an index of suspicion in clinicians to order the appropriate testing. Positivity of water culture sites should also be shared with administration to justify in-house availability of *Legionella*laboratory tests for patients with suspected pneumonia.[78,79]Additional information on performing environmental surveillance is available from informational websites such as www.legionella.org.

CULTURING THE POTABLE WATER DISTRIBUTION SYSTEM IN THE ABSENCE OF DISEASE

The most important risk factor for healthcare-associated legionellosis is the presence of *Legionella*in the hospital drinking water.[80]The 2004 recommendations—the latest guidelines published by the CDC—do not offer recommendations for routine culturing of a healthcare facility's water distribution system that does not have a high-risk population, such as transplant units.[81]Given that many hospital water systems

harbor *Legionella*and cases often go undiagnosed, this approach has not been successful in preventing outbreaks. Alternatively, when prospective surveillance of hospital drinking water has been performed, it has led to the discovery and prevention of healthcare-associated Legionnaires' disease.[39,40]For this reason, the states of Maryland and New York and the city of Pittsburgh (Allegheny County, Pennsylvania) and surrounding areas have adopted proactive guidelines for culturing hospital drinking water as a preventive measure even in the absence of known cases of healthcare-associated Legionnaires' disease.[82]Outside the United States, Germany, Italy, Spain, France, the Netherlands, and Denmark have also enacted proactive guidelines. Following the publication of guidelines to prevent *Legionella*in Italy in 2005, 129 healthcare facilities and 533 other buildings had their water systems cultured. Of these, 79 percent of the healthcare facilities and 45 percent of the other buildings had sites that were positive. During this time 97 cases of legionellosis were reported. Their findings confirmed the need to do routine environmental surveillance to control disease.[75]Evaluation of the effects of the Allegheny County (Pittsburgh, Pennsylvania) Health Department proactive guidelines on *Legionella*infections showed a significant decrease in healthcare-associated *Legionella*pneumonia. Cases decreased dramatically in the Pittsburgh area, from 33 to 9 percent ($p \leq .0001$).[73]Two unexpected benefits that arose from proactive surveillance were (1) in long-term care facilities, community-acquired *Legionella*pneumonia cases were found, as well as healthcare-associated cases; (2) unfavorable publicity and litigation involving Allegheny County medical facilities ceased.[73]If diligent monitoring and maintenance does not occur, outbreaks can easily be missed and become a legal nightmare. After a Taiwan investigator linked healthcare-associated Legionnaires' disease to the hospital's water supply, several hospitals initiated routine environmental surveillance and also found *Legionella*colonization.[83]

According to the World Health Organization (WHO), testing for *Legionella*is recommended as part of a risk management approach referred to as a water safety plan and would be performed under the following circumstances: (1) when water systems are treated with biocides and temperatures are lower than necessary for control; (2) in systems not achieving control through treatment programs; and (3) in hospital wards with high-risk patients. The WHO has published guidance on developing a water safety plan.[84]The typical elements of a water safety plan are to (1) describe the water system in sufficient detail that areas where water quality can be impacted are readily identifiable; (2) assess the risks for *Legionella*colonization and disease; (3) implement control measures to reduce the identified risks; and (4) perform annual reviews to verify that control measures are in fact controlling *Legionella*(see Figure 84-2). *Legionella*testing can provide evidence that the water safety plan is effective and that control measures are operating properly. It must be noted that while surrogate markers for the presence of *Legionella*have been sought (e.g., total bacterial counts and physicochemical parameters), none have been shown to reliably predict the presence/absence of *Legionella*. ATP testing of water is also not correlated to the presence/absence of *Legionella*and should not be used for this purpose. Knowledge of *Legionella*positivity in hospital drinking water is the only factor known with certainty to be predictive of risk for Legionnaires' disease.[85]

Interpretation of any testing results should take into account the risk profile of exposed patients and the proportion of positive sampling sites. Concentration-based targets (cfu/mL) have been used as an indicator of risk for legionellosis in many guidelines. In controlled studies specifically designed to assess the utility of cfu/mL targets, this parameter was found to fail to correlate with risk of disease. Numerous studies have found that the extent of colonization in a building is predictive of risk. When the distal site positivity of water fixtures exceeds 30 percent, the risk of hospital-associated legionellosis increases correspondingly. Although distal site positivity is not a foolproof cut point, a considerable amount of

evidence supports it as a pragmatic cut point. This was noted by Rivera et al. in a study in Spanish healthcare facilities. They asserted that the number of *Legionella*-disseminating points and the number of potentially exposed patients is a more important determinant of transmission risk than the dose (concentration).[86]Allen et al. published an article in which the authors purported to evaluate the accuracy of the 30 percent cut point for assessing the risk of Legionnaires' disease.[87]Unfortunately, no meaningful conclusions could be drawn because the study retrospectively applied the 30 percent criteria to studies where clinical surveillance was not conducted in parallel with environmental surveillance. Because concurrent surveillance was not performed for many of the studies that Allen et al. reviewed, it would be inaccurate to retroactively conclude that no cases of Legionnaires' disease occurred during the study period.

The sampling plan for environmental surveillance should include a minimum of 10 outlets plus the hot water tanks. Locations for sampling should roughly represent the water distribution system (i.e., sites on multiple floors and wings; high-risk areas such as hematology/oncology, transplant units, medical surgical units, and intensive care units). The complexity of the system will need to be taken into account in determining the appropriate number of samples to take. Swab and first draw hot water samples are typically collected. The sensitivity of each type of sample varies and the ability to concentrate water sometimes provides greater sensitivity. According to the CDC, volumes of water less than a liter are acceptable, and many laboratories use sample collection volumes of 250 mL.[88]Culture on selective media and use of pretreatment methods such as acid or heat treatment remains the recommended method for *Legionella*testing. According to the CDC, detection of *Legionella*species by direct fluorescent antibody staining is not suitable for environmental samples. PCR for identification of *Legionella*species is also not recommended.

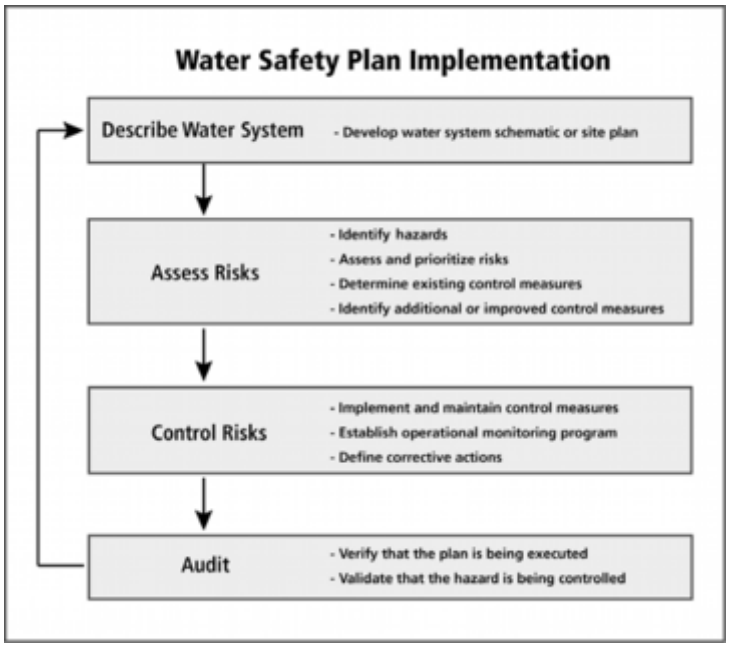

Figure 84-2.

Elements of a water safety plan for prevention of building-associated Legionnaires' disease.*Legionella*environmental testing aids in risk assessment and verifying controls are effective.

View Image

Standardized culture methods include ISO 11731: Detection and Enumeration of *Legionella*and CDC: Procedures for the Recovery of *Legionella*from the Environment.[88, 89]Laboratory results should include specific reporting of *Legionella*species and serogroups in addition to *L. pneumophila*serogroup 1. Laboratories may perform the testing with the requirements that they meet proficiency and quality performance standards through an approved accrediting body. Laboratories chosen for processing of water samples for *Legionella*should be experienced in *Legionella*isolation and specifically certified for proficiency in the CDC ELITE program, Public Health of England's (PHE) *Legionella*External Quality Assessment (EQA) scheme, or an equivalent program.

DISINFECTION OF HOSPITAL DRINKING WATER DISTRIBUTION SYSTEMS

There continue to be references in articles and guidelines to control measures that can be taken to minimize *Legionella*colonization of hospital water systems. These include maintenance of hot water tanks, removal and cleaning of aerators or showerheads, and removal of dead leg pipe. Unfortunately, these measures alone have not been shown to effectively reduce or control *Legionella*for any length of time.[90,91]Maintaining hot water temperature at 60°C (140°F) will minimize growth of *Legionella*.

It should be emphasized that this approach alone will not be effective unless systemwide disinfection has already been initiated.

When considering systemic disinfection, an evidence-based approach should be applied. The basis for decision-making for many hospitals in determining which type of system to implement and which commercial product to purchase includes anecdotal reports of success and unsubstantiated testimonials from commercial vendors. Any new disinfection method that is being considered for purchase should undergo a standardized evaluation with the following steps: (1) demonstrated efficacy in vitro against *Legionella*organisms, (2) anecdotal experience of efficacy in controlling *Legionella*contamination in individual hospitals, (3) controlled studies of prolonged duration (years, not months) of the efficacy of minimizing *Legionella*growth and preventing cases of Legionnaires' disease in individual hospitals, and (4) confirmatory reports from multiple hospitals with prolonged duration of follow-up or validation.[92]

Complete elimination of *Legionella*from a hospital water supply is not a realistic end point and has not been shown to be necessary to reduce or eliminate hospital-associated Legionnaires' disease.[92]There are now a number of options for short-term and long-term disinfection of water systems and these have been demonstrated to be effective in vitro and in the field.[93]Hospitals that install disinfection systems should monitor the disinfectant on a regular basis as well as perform periodic *Legionella*cultures to demonstrate effectiveness.[94]The selection of the disinfection system should be made in consultation with the infection preventionist, facility engineers, and the water safety team. Use of U.S. Environmental Protection Agency-registered and labeled disinfectants is recommended.

Superheat and Flush

If eradication is urgent, such as during an outbreak, superheating and flushing warrant primary consideration. Hot water temperatures are elevated to greater than 70°C (158°F) for 3 to 5 days with flushing of each hot-water faucet and showerhead for 30 minutes.[90]A 5- to 10-minute flush was erroneously recommended by the CDC,[76]and such shorter flush times have been shown to be ineffective.[90,95]The advantage of this method is that disinfection of the water distribution system can be instituted rapidly. Superheat and flush may be combined with shock hyperchlorination. This method is logistically tedious and the benefits are short-term; re-establishment of colonization invariably occurs. Superheating for treatment presents a challenge at distal taps where mixing valves are installed. These valves need to be bypassed in order to achieve the desired temperature. Caution is advised when superheating water due to risk of scald injury.

Copper-Silver Ionization Systems

Copper-silver ionization continuously releases copper and silver ions into the hot water system. The flow cell houses the metal electrodes and is typically installed on the hot water recirculation system. The positively charged copper and silver ions form bonds with the negatively charged ions on the bacterial cell wall, resulting in lysis and bacterial cell death. Monitoring ion concentrations and maintenance of equipment to reduce scale formation on the electrodes is necessary. Follow-up of 16 U.S. hospitals with

copper-silver ionization systems in place for 5 to 11 years has showed success where other methods such as chlorination had failed.[92]

Chlorine Dioxide

Chlorine dioxide can be used to disinfect both the cold and hot water systems. Unlike chlorine, chlorine dioxide does not form carcinogenic byproducts such as trihalomethanes.[96,97]It is odorless and tasteless and inhibits biofilm development. Chlorine dioxide has been shown to control *Legionella*, but more information is needed to ascertain long-term efficacy.[98,99]Methods for producing chlorine dioxide include controlled mixing of chemical precursors or electrochemical generation.

Monochloramine

Monochloramine is stable, prevents bacterial regrowth, and has the ability to penetrate biofilm more effectively than chlorine.[100,101]In one study, *Legionella*was not detected with sampling in medical facilities that received water from a municipality that treated water with monochloramine rather than free chlorine. Until recently the ability to generate and apply monochloramine on-site for disinfection of hospital water systems was not available. A monochloramine generation system is now available in the United States from an Italian company, and it has been evaluated for efficacy in controlling *Legionella*in two healthcare facilities—one Italian hospital and one hospital in Pittsburgh—over a 2-year period.[102,103]Both studies demonstrated effective control over prolonged duration.

Point-of-Use Water Filters

Point-of-use water filters have been used to effectively remove *Legionella*and other bacteria from water filtered through these devices.[104,105]The period of approved use of these devices has continually increased from the original 14-day use period to 61 days of use for the faucet filters. In addition to use for prevention of exposure to *Legionella*, they have also been used to prevent exposure to *Pseudomonas aeruginosa.*[106]In-line filters for ice machines are also available and can be used in high-risk units.

Hyperchlorination

Sustained hyperchlorination is not recommended because of marginal efficacy, corrosion to the plumbing system, and release of carcinogenic byproducts into the drinking water.

OTHER INFECTION PREVENTION MEASURES

Hands-free electronic sensor faucets have been an engineering intervention for infection prevention to limit hand contamination and to reduce water usage. However, since 2001 there have been reports of increased recovery of *Legionella*and *Pseudomonas aeruginosa*from these water fixtures.[107,108,109,110]The combination of mixing valves to reduce temperature and flow restriction to reduce water use produce an environment that may be more conducive to bacterial growth compared to manual-type faucets with separate hot and cold controls. Recommendations to restrict their use in high-risk areas have been made.

Other infection prevention measures include prohibiting the use of portable room humidifiers, rinsing respiratory equipment such as the ventilator bag apparatus with sterile water, using only sterile water to fill nebulizer reservoirs, prohibiting bathing of surgical wounds with tap water, and using sterile water to flush nasogastric tubes.[48,76,111]In an outbreak situation, sterile or bottled water should be considered for

drinking when caring for immunosuppressed patients. Many measures applied for prevention of healthcare-associated legionellosis are tedious, logistically difficult, and ineffective. Measures that are not evidence-based include prohibition of showering,[112] removal of dead legs in the plumbing system,[90] removal and cleaning of showerheads and faucet aerators,[90,95] routine maintenance, and periodic flushing of distal fixtures with hot water.

Standard Precautions are used with patients with *Legionella* infection; Isolation Precautions are not required because person-to-person spread does not occur. (See **29. Isolation Precautions (Transmission-based Precautions)**.)

EDUCATION

Although identification of *Legionella* species occurred more than 30 years ago, there continues to be fear and misunderstanding when Legionnaires' disease is diagnosed. Thus, it is imperative that both the medical facility's epidemiologist and infection preventionists institute educational measures if healthcare-associated legionellosis is occurring in a facility or during community outbreaks. Education should include healthcare personnel at all levels, including administrative staff, nursing staff, pharmacy, engineering, and housekeeping. Brochures and other handouts are useful tools for the education of patients and visitors if concerns are high in the community (e.g., documented or suspected outbreaks). A team approach is an excellent method for handling problems related to outbreaks of Legionnaires' disease or a contaminated water distribution system. In addition to the hospital epidemiologist (or chairman of the infection prevention committee) and the infection prevention staff, the team should include representation from administration, nursing, engineering, and other individuals in the medical facility who would be considered an asset to the program.

Conclusions

Legionnaires' disease is underdiagnosed because of a lack of availability of in-hospital diagnostic tests, especially *Legionella* culture on selective media. Proactive surveillance of hospital drinking water can confirm the presence of *Legionella*, help to assess the risk of healthcare-associated legionellosis, prompt a higher index of suspicion among clinicians, and provide evidence to justify the cost of implementing a potable water disinfection system. Disinfection systems for hospitals are being aggressively marketed; evidence-based criteria and documented hospital experience should be used as selection criteria of vendors. Cost is often a concern when administrators are faced with decisions regarding installation of new water disinfection systems and the maintenance and monitoring of any system. However, the increased morbidity and mortality and legal problems associated with healthcare-associated infections should negate any administrator's hesitancy.[113] Each healthcare facility should extend the activities of the environment-of-care team to include water safety to prevent and control exposures to waterborne pathogens such as *Legionella*.

Future Trends

Improved laboratory tests for diagnosis and environment surveillance need to be developed. PCR and other point-of-care testing for clinical specimens need to be validated.

International Perspective

Although *Legionella*infections have been reported from all inhabitable continents, most community-acquired outbreaks and clusters of healthcare-associated Legionnaires' disease have been reported from North America and Europe. Regional differences in disease incidence exist, but it is likely that cases from the rest of the world are significantly underreported. More cases of illness due to non-*pneumophila*species, such as *Legionella longbeachae,*have been reported in Europe.

APIC TEXT OF INFECTION CONTROL AND EPIDEMIOLOGY

Lyme Disease (Borrelia burgdorferi)

Author(s): Kathleen Roye-Horn, RN, CIC

Horn IP Consulting
Fleming, NJ

Published: October 3, 2014

Abstract

Lyme disease is a multisystem disease that occurs in North America, Europe, and Asia; it is the most common tickborne disease in the United States and is endemic in several areas. The number of reported cases has increased steadily since 1982, when systematic national surveillance was initiated; the actual number of patients diagnosed with Lyme disease is thought to be much higher than the reported number. Most individuals diagnosed early with the characteristic rash, erythema migrans, respond well to short courses of oral antibiotics. In patients who present with later stages of illness, the diagnosis is based on clinical and epidemiological evidence of disease and is supported by serologic testing. Accurate diagnosis is possible through use of a two-tiered antibody test. The stage and organ system involved guide the selection of an antibiotic regimen. Untreated infection can spread to joints, the heart, and the nervous system. Personal protective measures are important for prevention of infection. Lyme disease is a national notifiable disease (voluntary); however, many states require mandatory surveillance and reporting.

Key Concepts

- Lyme disease is the most common tickborne disease in the United States.
- Black-legged ticks (deer ticks) act as vectors to transmit *Borrelia burgdorferi*, the causative agent of Lyme disease.
- Lyme disease is associated with a variety of symptoms.
- Lyme disease can be reliably diagnosed.
- Effective antimicrobial therapy is available to treat Lyme disease.
- Patients with Lyme disease may be co-infected with other tickborne diseases.
- Methods exist to reduce the risk of exposure to infected ticks.

- Lyme disease is reportable in the United States.

Background

Lyme disease, a systemic illness caused by the spirochete *Borrelia burgdorferi,*is the most common tickborne disease in the United States. In 2011, 47 states reported 33,097 cases of Lyme disease that fulfilled the Centers for Disease Control and Prevention (CDC) surveillance case definition; it was the sixth most common notifiable disease.[1]Lyme disease primarily affects the skin, heart, joints, and nervous system and is often divided into early and late stages.[2]The earliest manifestation is the skin lesion erythema migrans, which appears as an expanding erythematous skin lesion at the site of a deer tick bite.[3]

Basic Principles

Lyme disease is caused by a coiled spirochete, *B. burgdorferi,*named for its discoverer, Willy Burgdorfer, PhD.[4,5]Allen Steere, MD, clinically described the disease as an infectious illness in 1977, suggesting that its epidemiology indicated involvement of an arthropod vector due to its seasonality and clustering in rural areas. Burgdorfer subsequently observed the spirochetes in midgut tissue taken from ticks collected in a Lyme-endemic area and produced the characteristic skin rash in injected rabbits. The organism has since been cultured from the blood, skin, synovial fluid, and cerebrospinal fluid (CSF) of infected patients.[6,7,8]With the exception of skin biopsy specimens, it is difficult to culture *B. burgdorferi*from sites of infection.

*B. burgdorferi*displays phenotypic and genotypic diversity and has been classified into separate genospecies. The three principal species associated with human disease are *B. burgdorferisensu stricto*, which includes all strains studied thus far from the United States and some European and Asian strains, and *B. garinii*and *B. afzelii,*both of which include strains from Europe and Asia.[9,10]The three *Borrelia*species are collectively referred to as *B. burgdorferisensu lato*. Disease expression is thought to be related to differences in genospecies.[10]

*B. burgdorferi*is transmitted through the skin of the host via a tick bite. After an incubation period of several days to weeks, the organism migrates outward in the skin, producing the characteristic skin rash, erythema migrans. In some patients, the organism spreads in lymph nodes (regional lymphadenopathy) or hematologically disseminates to other organs (liver, heart, brain, joints) or skin sites (secondary skin lesions).[11]

The presence of *B. burgdorferi*elicits strong host immune responses, with the subsequent release of inflammatory mediators. Histopathologic studies have indicated that mixed, predominantly mononuclear cellular infiltrates with monocytes/macrophages, but also T and B lymphocytes, are present in infected tissues.[12]It is believed that a combined effect of local spirochetal infection with an intense immunologic reaction to the organism is responsible for disease expression.

Anti-*Borrelia*antibodies are produced in response to infection. In serum, specific immunoglobulin M (IgM) antibody titers against *B. burgdorferi*usually reach a peak between the third and sixth week after the

onset of disease; specific immunoglobin G (IgG) antibody titers rise more slowly and are generally highest months later, when arthritis may be present. Antibodies are typically detected with two-tier serologic testing using an enzyme-linked immunosorbent assay (ELISA) or immunofluorescence assay, followed by a Western blot for confirmation when the ELISA is positive or equivocal.[13,14] Antibody titers may persist for months to years after successful disease therapy.[15,16]

EPIDEMIOLOGY

Lyme disease is distributed worldwide. The majority of cases occur in temperate regions and coincide with the presence of principal tick vectors such as *Ixodes ricinus* in Europe and *Ixodes persulcatus* in Eastern Europe and Asia.[17] In the United States, Lyme disease has been reported in all 50 states but occurs most commonly in three principal areas: New England and the Mid-Atlantic states, the upper Midwest with concentration in the Great Lakes region, and several counties in northern California; 96 percent of all reported cases are from 13 states.[1] These areas correspond to the distribution of the predominant tick vectors of Lyme disease in the United States—*Ixodes scapularis* (eastern black-legged tick) in the East and Midwest, and *Ixodes pacificus* (western black-legged tick) in the West. *Ixodes* ticks typically become infected with spirochetes during the larval and nymphal stages by feeding on a spirochetemic host, which serves as a reservoir.[18] The CDC, using medical insurance claims plus clinical laboratory data and self-reported cases from a survey of the general public, estimates that the number of diagnosed Lyme disease cases in the United States each year is around 300,000; this is a tenfold difference from the number of cases reported through the national surveillance system.[19]

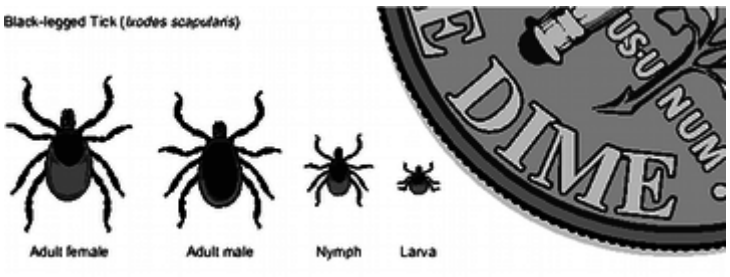

Figure 85-1.

Lyme disease map 2011. Though Lyme disease cases have been reported in nearly every state, cases are reported from the infected person's county of residence, not the place where they were infected. (Source: **www.cdc.gov/lyme/stats/maps/** **View Image**

Ixodes scapularis has a three-stage, 2-year life cycle. *I. scapularis* feeds from spring through fall but may be active on warm winter days. The preferred host is the white-footed mouse in the larval and nymphal stages and white-tailed deer in the adult stage. In highly endemic areas, from 10 to more than 50 percent of *I. scapularis* ticks carry *B. burgdorferi*.[20] *Ixodes pacificus* completes its life cycle in 3 years, feeding on black-tailed deer and other large mammals as an adult and small mammals, birds, and lizards in its larval and nymphal stages. Early stages feed spring through fall, but adults are most active in winter.[21]

Figure 85-2.

Black-legged tick. Relative sizes of several ticks at different life stages. In general, adult ticks are approximately the size of a sesame seed and nymphal ticks are approximately the size of a poppy

seed. (Source: www.cdc.gov/lyme/transmissic View Image

The Lyme disease spirochete is maintained naturally in enzootic cycles requiring vector ticks, reservoir animals, and maintenance hosts. Humans are only an incidental host of the tick, with contact typically made in areas of underbrush, leaf litter, or high grasses. Rarely, tick exposure may occur in well-mown lawns in endemic areas, especially if those lawns are moist and shady. Ticks are found around the edges of cut lawns that are within 10 feet of tick habitats. Lyme disease affects all age groups, though the greatest number of cases occurs in children 5 to 9 years of age and adults aged 55 to 59 years of age.[1]The incidence of exposure (early manifestation) peaks from June to August, coinciding with periods when nymphal ticks are feeding, and tapers off in the early fall. Adult ticks, abundant during the early and late fall in the East and in winter in the West, are less likely to transmit the disease to humans because they prefer deer as hosts and are more readily detected and removed from humans. Animal models have demonstrated that transmission is unlikely to occur before a minimum of 36 hours of tick attachment and feeding.[22,23]This is not the case for other tickborne diseases, however, in which transmission can occur after a brief period of attachment.[21]

Only 25 percent of patients with erythema migrans recall the tick bite that transmitted disease.[14,24]This likely reflects the small size of the tick and the lack of pain or pruritus generally associated with the bite. In addition, the tick often attaches at a site that may not be easily visualized by the host. Individuals who have multiple tick exposures may develop an allergic response to the bite, which alerts them to the presence of the tick. Whether due to early tick removal or the immune response at the site, these individuals are less likely to develop Lyme disease.[25]

CLINICAL MANIFESTATIONS

Lyme disease is typically divided into three clinical stages, which are termed early localized, early disseminated, and late disseminated infection. Overlap of these stages may occur, and most patients do not exhibit all stages; in fact, seroconversion can occur in asymptomatic individuals.[26]In highly endemic areas of the United States, seropositivity rates of greater than 4 percent have been documented, with even higher rates occurring in Europe.[10]

Early Localized Lyme Disease

Erythema migrans, the most distinct clinical marker for Lyme disease, begins at the site of the tick bite 7 to 14 days (range, 3 to 30 days) after tick detachment. It appears as an expanding erythematous skin lesion, usually round or oval, which may eventually develop central clearing over days to weeks if untreated.[27,28]The CDC recommends using a 5-cm minimum for erythema migrans lesions to help distinguish it from other types of reactions. Lesions can range widely in size, with size being a function of duration, but size is unrelated to prognosis.[24]The thigh, groin, popliteal fossa, back, abdomen, and axilla are common sites of erythema migrans; these sites would be unusual for community-acquired cellulitis. The lesion may be warm to the touch but is generally asymptomatic and easily missed if not seen. Occasionally these lesions may develop blistering or scabbing in the center; remain an even, intense red without clearing; or develop a bluish discoloration.[29,30]Although spirochetes can be readily

cultured from the expanding edge of erythema migrans lesions, visualization of the characteristic rash by an experienced practitioner is sufficient for diagnosis.[14,31] Untreated erythema migrans resolves after several weeks, and treated lesions usually clear within several days.

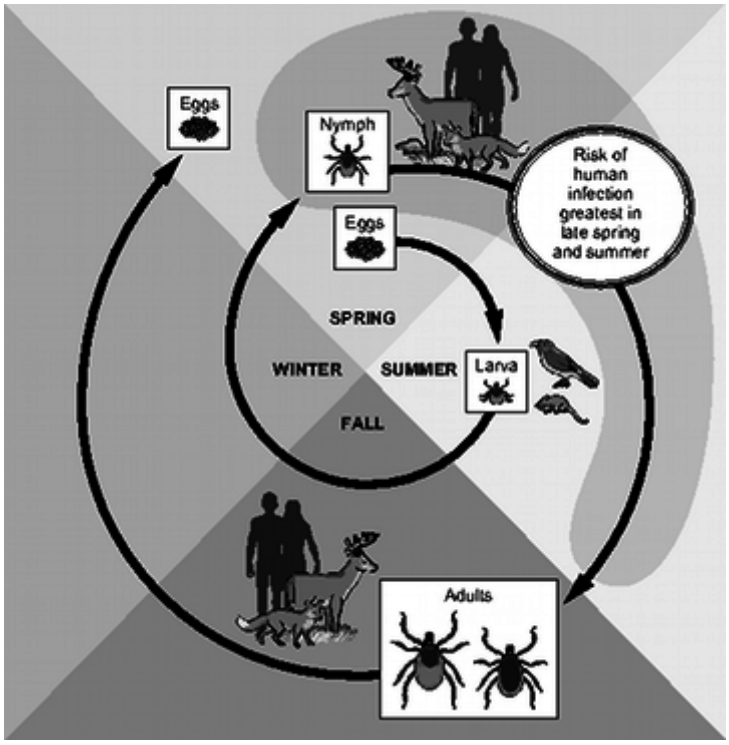

Figure 85-3. Life cycle of black-legged tick. This diagram shows the lifecycle of black-legged ticks that can transmit Lyme dis View Image

Figure 85-3. Life cycle of black-legged tick. This diagram shows the lifecycle of black-legged ticks that can transmit Lyme disease. (Source: **www.cdc.gov/lyme/transmission/black-legged.html**)

An erythematous reaction that develops while the tick is still attached or within the first 48 hours after detachment is likely to be a noninfectious hypersensitivity reaction to the tick bite. A lesion smaller than 5 cm that begins to disappear within 24 to 48 hours may be a transient inflammatory reaction to an arthropod bite.[14,28]

A rash that has been mistaken for Lyme's erythema migrans occurs after the bite of the *Amblyomma americanum,* or lone star, tick. Found mainly in the southeast and south central United States, the lone star tick cannot transmit Lyme disease but is the vector of other tickborne diseases.[32]

Early Disseminated Lyme Disease

Secondary skin lesions may develop within days of onset of erythema migrans; spread is thought to be via hematogenous dissemination from the site of primary infection.[33] The lesions are similar in appearance to erythema migrans but are generally smaller and uniformly erythematous. Skin involvement is often accompanied by flulike symptoms (malaise, fatigue, headache, fever, chills, myalgia, and arthralgia). Mild hepatitis, splenomegaly, sore throat, nonproductive cough, testicular swelling, conjunctivitis, and regional and generalized lymphadenopathy may also occur during early stages.[30]

Peripheral or central nervous system (CNS) involvement can occur early or late in disease and affects 15 to 20 percent of untreated patients. Unilateral or bilateral seventh-nerve (facial) palsies are the most common neurologic abnormalities. Less frequent involvement includes meningitis or meningoencephalitis, cranial neuritis, and peripheral neuritis or radiculitis. Analysis of CSF typically reveals a lymphocytic pleocytosis, protein elevation, and specific antibodies against *B. burgdorferi.* Lyme encephalitis is extremely rare. Neurologic abnormalities usually resolve completely but may persist for months.[8]

Cardiac involvement is estimated to occur in 4 to 10 percent of untreated patients. It is typically seen from June through December, 4 days to 7 months after the tick bite or erythema migrans. Transient and varying degrees of atrioventricular block are the most common manifestations. Rarely pericarditis, myocarditis, ventricular tachycardia, or cardiomegaly is seen. Acute carditis is typically self-limited,

though some patients require the insertion of a temporary pacemaker for high-degree atrioventricular block. Long-term sequelae or late complications are rare.[3,34]

Because other *Borrelia*species cause disease in Europe, manifestations of disease there differ. A rare cutaneous manifestation of Lyme disease seen in 3 percent of patients in Europe is *Borrelia*lymphocytoma. This presents as a solitary bluish-red swollen lesion typically on the earlobe in children and on the breast, nipple, or scrotum in adults. It generally appears later and lasts longer than the original erythema migrans.[35,36]

Late Disseminated Lyme Disease

If left untreated, late disseminated Lyme infection causes pain and joint swelling in 60 percent of cases. This sequence is seen much less frequently today than 20 years ago, probably due to earlier recognition and treatment. The initial pattern of joint involvement consists of migratory arthralgias followed by intermittent attacks of arthritis lasting from days to months. Large joints are most commonly involved, particularly knees and hips; however, other large joints or the temporomandibular joint may be involved. Knee swelling is often prominent, with the development of large effusions and Baker cysts.[21,37]

Response to antibiotics is typically excellent, though effusions may take months to completely resolve. Persistent pain and swelling in the same joint for a period longer than a year is unusual for Lyme disease and would suggest another diagnosis.[14,33]

A subgroup of patients with Lyme arthritis develops a chronic, potentially erosive arthritis that persists after resolution of infection. The risk of this chronic, noninfectious arthritis is high in patients with the alloantigen HLA-DR4, whereas patients with HLA-B27 are not at risk.[38]Synovectomy has been successful in treating patients who experience failed treatment for inflammatory arthritis.[39,40]

Late neurologic Lyme disease is now a rare occurrence because most patients with Lyme disease are diagnosed and treated early. A small number of patients will, if left untreated, progress to have encephalomyelitis, peripheral neuropathy, or encephalopathy. Standard antibiotic therapy is generally successful in resolution of CNS disease.[14]In patients with symptoms suggestive of late neurologic Lyme disease, it is important to rule out other possible causes, such as multiple sclerosis.[8,41]

Before the availability of confirmatory diagnostic tests, ocular problems, particularly optic neuritis occurring in seropositive patients in Lyme disease-endemic areas, were often thought to be attributable to Lyme disease. Since confirmation of positive antibody tests with immunoblotting has become the standard, eye disease is recognized as a rare complication. The most common manifestation is in children with early disseminated disease involving a meningitis, papilledema, and increased intracranial pressure. When optic neuritis does occur, it generally presents as a unilateral or bilateral papillitis during the early disseminated stage.[42,43]

Pregnancy

Prenatal exposure to Lyme disease has not been found to be associated with an increased risk of adverse pregnancy outcome.[44]Lyme disease acquired during pregnancy and left untreated may lead to infection of the placenta and possible stillbirth; however, no negative effects on the fetus have been found when the mother receives appropriate antibiotic therapy. Maternal-to-fetal transmission has been documented in only three cases; in each of these cases, treatment was lacking or inadequate. Chronic

congenital Lyme disease has never been documented. There are no reports of Lyme disease transmission from breast milk.[45,46]

Persistent Symptoms

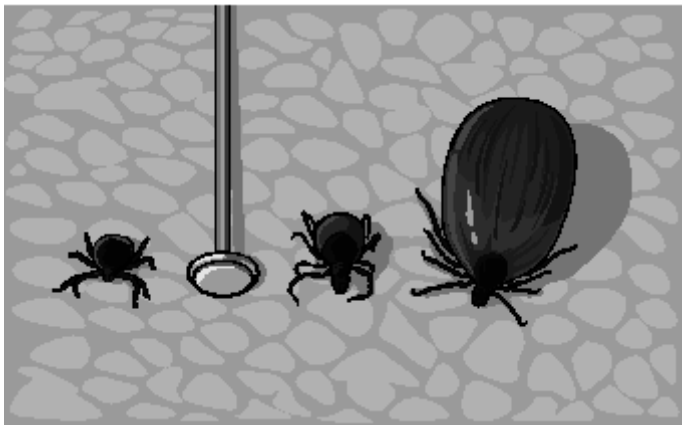
Leonard Sigal, MD, was quoted in the *New York Times* in 2001 as saying, "Lyme disease, although a problem, is not nearly as big a problem as most people think. The bigger problem is Lyme anxiety."[46]

Although this anxiety can be attributed in part to misinformation in the lay press and on the Internet, another factor may be that a small subset of treated patients experience persistent symptoms, such as fatigue, myalgias, arthralgias, dysesthesias, and/or mood and memory disturbances. These symptoms continue after the prescribed antibiotic regimen is finished, lasting for weeks or months. This discord between antibiotic therapy ending and symptoms continuing leads patients to worry that infection is still present and further treatment is warranted. Although the etiology of such symptoms is unclear, studies have repeatedly shown that prolonged or repeated courses of antibiotics are not necessary, can cause harm, and do not hasten resolution of these symptoms.[41,47,48] One tool to offer patients in this situation is use of a personal diary in which they note symptoms daily; they can then look back in the diary and see that they are making slow progress, which might not otherwise be apparent to them.

The symptoms mentioned are generally mild and self-limiting, lasting less than 6 months, and have been referred to as "post-Lyme disease symptoms," reflecting that symptoms persist after the infection is no longer present. When symptoms are reported to be more severe and last more than 6 months after diagnosis, terms such as "post-Lyme disease syndrome," "posttreatment chronic Lyme disease," and "chronic Lyme disease" have been applied. Studies of patients with post-Lyme disease complaints have used varied case definitions, enrollment criteria, and patient populations. In some cases, the term has been applied to patients who have not been diagnosed using standard methods or who have not been adequately treated. Some patients in this group may have coinfection, with another tickborne disease causing their symptomatology. Patients with joint complaints may have a degree of joint erosion causing their pain. Neither laboratory studies nor treatment trials done with scientific rigor support the persistence of *B. burgdorferi* infection in patients who have received adequate therapy.[41,47,48]

Reinfection

Reinfection with Lyme disease has been well documented in Lyme-endemic areas. This occurs in patients who are treated with antibiotics in early-stage disease, generally with erythema migrans only, before a protective immune response can develop. Reinfection in patients with more advanced Lyme disease, with late manifestations such as Lyme arthritis or neurological disease, is rare or does not occur.[10,49]



DIAGNOSIS

One step in evaluating the potential for Lyme disease is to determine if the patient had a bite from a tick capable of transmitting Lyme disease. Healthcare providers in endemic areas should learn to identify these *Ixodes* ticks and to estimate the degree of engorgement as a marker of feeding time.[21] Testing ticks removed from patients for *Borrelia* is not recommended.[14,21,23]

View Image

Early Disease

Erythema migrans, present in about 90 percent of cases, is diagnostic of Lyme disease.[11,26] *B. burgdorferi* can be cultured from skin lesions, but the test is not readily available and is unnecessary for routine patient care. A history of a tick bite and residence or travel in an endemic area should be sought in patients complaining of a summer flulike illness with fever, chills, myalgias, fatigue, headache, and malaise. Serologic tests typically are negative during this stage because a measurable antibody response takes weeks to develop. If serologic tests are done at this stage, convalescent testing should be repeated in 2 to 6 weeks.[10]

Specific IgM antibody responses against *B. burgdorferi* develop 2 to 4 weeks after the onset of erythema migrans. This reflects the normal humoral antibody lag time between infection onset and detectable serum antibody levels.[41] IgG antibody levels appear approximately 6 weeks after disease onset but may not peak until months or even years later. Patients receiving antibiotics for erythema migrans may never have measurable antibody responses.

Established Disease

Specific antibody testing is helpful in establishing the diagnosis in patients with cardiac, neurologic, or arthritic manifestations. In almost all such patients, specific IgG antibody responses will be positive. Laboratory diagnosis is limited by false-positive results related to mononucleosis, syphilis, or certain autoimmune diseases; interlaboratory variability; seropositive test results among asymptomatic persons residing in endemic areas; receipt of the Lyme vaccine prior to 2002; and difficulty distinguishing past from current infections.[11,48,50]

Guidelines have been published for laboratory evaluation and interpretation in the diagnosis of Lyme disease.[13,50,51] Recommendations include testing only patients with clear clinical symptoms of Lyme disease; using a two-test protocol in which either positive or indeterminant ELISA or immunofluorescence assays are followed by Western blot confirmatory testing; withholding Lyme disease antibiotic therapy from patients with only vague symptoms, such as malaise, when the probability of Lyme disease is low; and providing empirical antibiotic therapy for patients who present with a rash resembling erythema migrans if they live in or have visited a high-risk area.

In patients with suspected Lyme arthritis or neurologic Lyme disease, the Infectious Disease Society of America recommends testing CSF for intrathecal antibodies. Polymerase chain reaction testing is also an option in these patients.[14]

Alternative Methods of Detection

Various assays have been proposed for use in confirming the diagnosis of Lyme disease. These include reverse Western blots, lymphocyte transformation tests, borreliacidal antibody assay, immune complex disruption, and T-cell proliferative responses. These tests have not been sufficiently studied to become a standard part of routine clinical diagnostic testing of Lyme disease. The C6 antibody test is a relatively new form of ELISA that identifies a specific region of *Borrelia* protein; it has improved specificity with

similar sensitivity to that of the IgM ELISA when used in early disease.[26] The Lyme urine antigen test is not approved for use by the U.S. Food and Drug Administration (FDA) and is not recommended by the CDC or the American Lyme Disease Foundation for patient diagnosis or care; it has a high false-positive rate.[2,11]

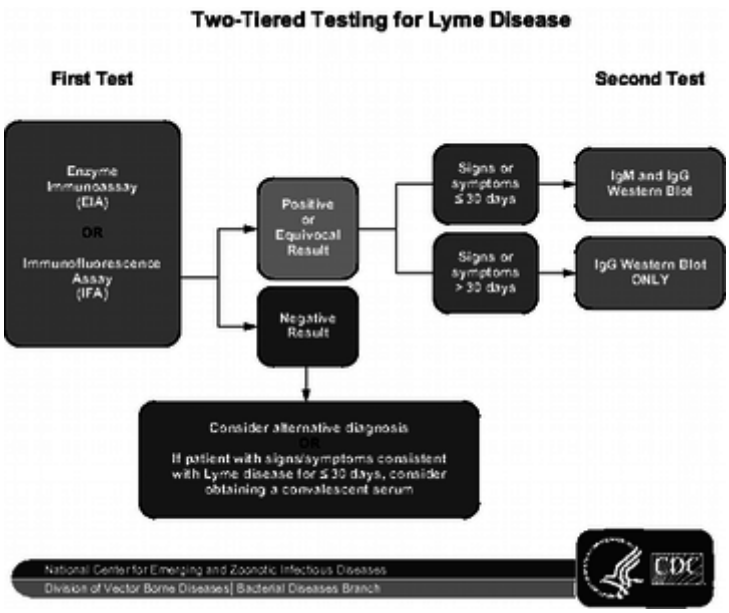

Figure 85-5.

Two tier testing. The Two-tier Testing Decision Tree describes the steps required to properly test for Lyme disease.(Source: www.cdc.gov/lyme/healthcare/clinician_twotier.html)

View Image

TREATMENT

Lyme *Borrelia*is very sensitive to treatment with the tetracyclines, most penicillins, second- and third-generation cephalosporins and, to a lesser degree, macrolides. Resistance has been shown to first-generation cephalosporins, certain fluoroquinolones, and rifampin.[10]

Erythema Migrans and Early Disease

Doxycycline 100 mg by mouth twice daily or amoxicillin 500 mg three times a day for 10 to 21 days are agents of choice. Doxycycline is not recommended for children younger than 8 years or pregnant or lactating women. Cefuroxime axetil 500 mg twice daily for 14 to 21 days and azithromycin 500 mg daily for 7 to 10 days are appropriate for patients who are allergic to penicillin and who cannot take tetracyclines.

Neurologic Manifestations

1. Facial palsy alone may be treated with oral antibiotics as recommended for early disease.
2. Other manifestations: ceftriaxone 2 g/day intravenously (IV) for 14 to 28 days with cefotaxime 2 g every 8 hours IV or penicillin G 20 million units IV daily for 14 to 28 days as an alternative

Lyme Carditis

1. Mild (first-degree atrial-ventricular [AV] block): doxycycline 100 mg twice daily for 14 to 21 days or amoxicillin 500 mg three times daily for 14 to 21 days
2. Moderate to severe: ceftriaxone 2 g/day for 14 to 21 days or cefotaxime 2 g every 8 hours IV daily for 14 to 28 days

Lyme Arthritis

1. Doxycycline 100 mg twice daily or amoxicillin 500 mg three times a day for 28 days
2. Ceftriaxone 2 g/day IV for 14 to 28 days

Pediatric dosages differ from those provided here.[14,35]

[35]

Pregnancy

Treatment during pregnancy is as described above, except doxycycline should not be used due to potential side effects to both the mother and fetus.[10]

Prevention And Protection

Prevention of Lyme disease is best accomplished by preventing tick bites. Although prevention of Lyme disease is itself an important goal, successful strategies can be expected to have the additional benefit of preventing other tickborne diseases. Methods for reducing the risk of Lyme disease include vector control and personal protection, including antibiotic prophylaxis in select cases.

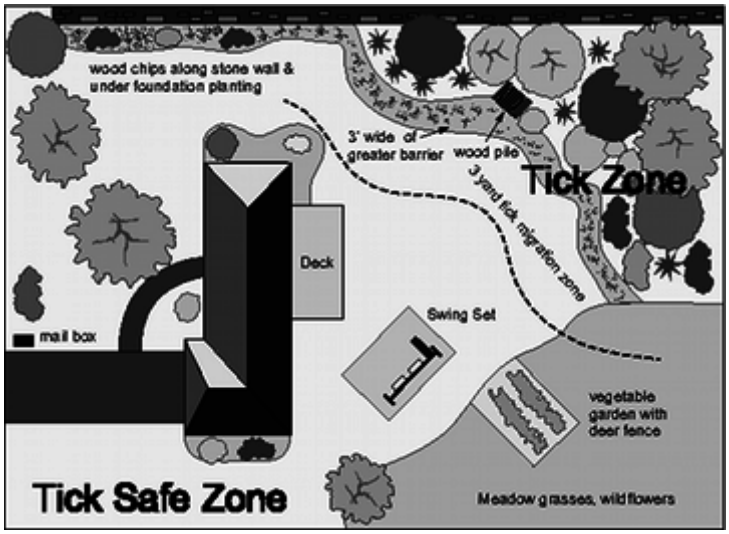

Figure 85-6.

Tick safe zone. Reducing tick habitat. (Source: **www.cdc.gov/lyme/prev/in_the** View Image

Tick habitat alteration can work in limited areas, such as backyards and residential areas. Removing leaf litter and mowing in areas of human activity are effective in destroying tick habitat and reducing tick numbers; one study found a 73 to 100 percent reduction in tick density when leaf litter removal was done in March and June.[52,53]Targeted application of acaricides such as permethrin, deltamethrin, carbaryl, diazinon, chlorpyrifos, or cyfluthrin to tick habitats that are shared/used by humans is also effective, reducing tick populations by as much as 100 percent for as long as 12 weeks.[52,54]These are most effective when applied in the early spring and fall. There are a number of drawbacks to these applications: these products kill more than the intended ticks; timing is critical; they hold the potential for human harm; and there is early evidence of resistance developing.[52,55,56,57]

Public health prevention efforts have focused on enhancing general knowledge of Lyme disease, tick avoidance, and promoting precautionary behavior, such as repellent use and daily tick checks for individuals living or vacationing in endemic areas. Personal protection includes wearing light-colored clothing in order to find ticks more easily, tucking pant cuffs into socks to keep ticks from gaining access to exposed skin, using tick or insect repellents, and performing tick checks.[21]Repellents containing N,N-Diethyl-meta-toluamide (DEET) are very effective against ticks when applied to the skin, significantly

reducing both the number and frequency of tick bites. They are available in 5 to 100 percent formulations, with a formulation up to 30 percent recommended for adults and children over 2 years old. Higher concentrations produce a more long-lasting effect but are not recommended for children. DEET is safe when used according to the manufacturers' directions. Adults should apply DEET to children so the product is less likely to get into their eyes and mouth. Combination products of DEET and sunscreen are not recommended, as DEET is not water-soluble and could reach problematic levels if re-applied for sun protection.

Picaridin is another effective skin product; it requires more frequent application but has the advantage of being safe to use on plastics, such as eyeglasses, which can be damaged by DEET-containing products. Other repellents commonly marketed as being tick repellents are not as effective as DEET and picaridin; these include garlic, eucalyptus oil, and citronella, all of which do repel mosquitoes.

According to the American Academy of Pediatrics, insect repellents should not be used on children under 2 months of age.

Permethrin-based repellents can be used on clothing and fabric of outdoor equipment such as tents and mosquito netting. An insecticide, it kills ticks and mosquitoes on contact. It is applied by spray or immersion and retains its acaricidal properties through multiple launderings.[21,52]Clothing should be treated before it is put on and allowed to dry for 2 to 4 hours. Permethrin should not be applied to skin.[21]

Showering within 2 hours of tick exposure and performing daily tick checks after being outdoors in tick habitats are thought to have some benefit in preventing Lyme disease. Because movement of *B. burgdorferi*from the feeding tick's midgut to its salivary glands then into the host takes at least 36 hours, finding and removing the tick prior to that may provide some protection.[52]Ticks can be very difficult to find, however, and adherence to daily checks can be difficult.[26]In a study published in *Emerging Infectious Diseases*in February 2008, wearing long clothing that decreases the area of exposed skin and using repellents on skin or clothing were shown to be more effective prevention methods than doing tick checks or using acaricides on property.[58]

Antibiotic prophylaxis to prevent Lyme disease after a known tick bite is not routinely warranted. The risk of infection from a deer tick bite in a Lyme disease-endemic area is low. A cost-benefit analysis of antibiotic prophylaxis for Lyme disease following tick attachment found that prophylaxis is warranted if the incidence of Lyme disease following tick bite is at least 3.6 percent.[59]One randomized, double-blind trial of patients residing in an endemic area from whom *I. scapularis*ticks had been removed within 72 hours found that a single dose of 200 mg of doxycycline was effective in preventing Lyme disease when compared with placebo.[60]Therefore, in an area endemic for Lyme disease (greater than 20 percent of ticks infected with *Borrelia*), single-dose antibiotic prophylaxis can be considered for individuals with an *Ixodes*tick attached for more than 36 hours when prophylaxis can begin within 72 hours of tick removal.[52]

Individuals who received the recombinant OspA Lyme disease vaccine when it was available from 1998 to 2002 are unlikely to have current protection because its protective effect was not long lasting.[61,62]

Since the vaccine was withdrawn from the market in 2002 due to poor sales and fear of side effects, research has continued on development of a Lyme disease vaccine. Lyme disease vaccines have been

available for dogs since 1990 and continue in use.[26] New human vaccines are being studied using different *Borrelia* antigens and new, innovative technologies are being considered, such as vaccinating against the tick itself or vaccinating a major reservoir, the *Peromyscus* mouse, to reduce carriage of the organism.[52,63]

Co-Infection

I. scapularis ticks serve as vectors not only of *B. burgdorferi* but also of *Anaplasma phagocytophilum* and *Babesia microti*, agents of human granulocytic anaplasmosis (formerly called human granulocytic ehrlichiosis) and babesiosis. Transmission of these organisms can result in single infections following a tick bite, or infections can occur in combination, resulting in co-infection.[14,21,32] When symptoms inconsistent with Lyme disease, such a high fever, occur in a patient diagnosed with Lyme disease, co-infection must be considered so that appropriate diagnostic and treatment decisions can be made. In areas with significant risk of these diseases, or when tick studies have indicated the presence of these organisms in the environment, consideration should be given to routine testing for co-infection with multiple tickborne pathogens.[10,21,26,32]

Lyme Disease As A Reportable Disease

Lyme disease is a nationally notifiable disease. Although national reporting is voluntary, many states have made Lyme disease reportable by regulation. The surveillance case definition was developed for national reporting of Lyme disease and is not intended for use in clinical diagnosis; it was revised in 2011. Confirmed and probable cases are reportable, using the case definition that can be found on the CDC website. (See Supplemental Resource.)

Conclusions

Lyme disease is the most common tickborne disease in the United States. Most individuals diagnosed early with erythema migrans are cured following short courses of oral antibiotics. The stage and organ system involved guide the selection of an antibiotic regimen in disseminated disease. Although there can be chronic sequelae following infection, cure rates are high for all stages. Prolonged or repeated courses of antibiotic show no benefit when symptoms remain. Personal protective measures are important for prevention of infection. Prevention methods include vector control and personal protection. Public health prevention efforts have focused on enhancing general knowledge of Lyme disease, tick avoidance, and promoting precautionary behavior, such as use of repellents and daily tick checks. Antibiotic prophylaxis to prevent Lyme disease after a known tick bite is warranted in select cases. Currently there are no Lyme disease vaccines commercially available for use in humans.

Chapter Overview

This chapter covers three distinct viral diseases that are prevented with a combined and effective vaccine. For convenience, the chapter is separated into three sections to more suitably discuss the uniqueness of each disease entity—measles, mumps, and rubella.

Abstract—Measles

Measles is a highly contagious febrile exanthem. In most immunocompetent individuals, measles is a self-limited condition with a distinct clinical prodrome of cough, coryza, and conjunctivitis followed by a morbilliform skin eruption. Measles is more severe in young, malnourished, and immunocompromised individuals. Even healthy individuals may experience complications, such as otitis media, bronchopneumonia, encephalitis, and laryngotracheobronchitis. A live virus vaccine to prevent measles has been available since 1963 and has resulted in substantial reduction (approaching 99 percent) of measles in countries with active measles vaccine programs. Despite the availability of this effective vaccine, measles still causes significant morbidity and mortality worldwide, especially in nonindustrialized nations. Measles occurs only in humans (no animal reservoir), and the current vaccine is highly effective. For these reasons, the World Health Organization (WHO) has targeted measles for global elimination. Because measles is so highly contagious, healthcare facilities need to be prepared to safely care for measles patients. Measles immunity (natural or vaccinated) among healthcare personnel and use of proper isolation guidelines and postexposure protocols need to be established to minimize the potential for healthcare-associated transmission of measles.

Key Concepts—Measles

• Measles is a highly contagious febrile exanthema.

• The live vaccine significantly reduced measles in nations with high vaccine coverage and resulted in a 71 percent decrease in measles deaths between 2000 and 2011 worldwide, as well as a decrease of approximately 90 percent in the eastern Mediterranean and Africa regions.

• Morbidity and mortality are still high in nonindustrialized nations.

• Complications can occur in malnourished, pregnant, immunocompromised, and young patients.

Background—Measles

Measles (rubeola, 7-day measles) is a distinct clinical syndrome with a characteristic prodrome of respiratory tract symptoms (cough, coryza, and conjunctivitis), followed by a febrile exanthem and a recovery period that includes a persistent cough for many weeks. Measles occurs throughout the world. It is one of the most highly contagious infectious diseases in humans. In parts of the world where measles vaccination has been instituted, the incidence of measles has decreased substantially. In much of the nonindustrialized world, measles is still responsible for significant morbidity and mortality. It remains a leading cause of death among young children globally, despite the availability of a safe and effective vaccine. An estimated 159,000 people died of measles in 2011; mostly children under 5 years of age.**a**

Basic Principles—Measles

The measles virus is a ribonucleic acid (RNA)-containing paramyxovirus with one serotype, classified in the genus *Morbillivirus*in the family Paramyxoviridae.[1,2,3,4]It is an enveloped, nonsegmented, single-stranded, negative-sense RNA virus. Measles is antigenically distinct from, but related closely to, canine distemper virus and rinderpest virus.[1]Humans are the only natural host for wild measles virus.[5]Measles virus, in contrast with other paramyxoviruses, does not contain specific neuraminidase activity, and it does not adsorb to neuraminic acid–containing cellular receptors.[1]Measles virus hemagglutinates red blood cells, but other *Morbillivirus*spp. do not.

Epidemiology—Measles

Measles has been recognized as a disease for approximately 2,000 years. In the ninth century, Rhazes, a Persian physician from Baghdad, provided the first written account of measles.[6]The first account of measles in North America was described in Boston in 1657 by John Hall.[7]It was not until 1955, however, when Enders and Peebles[8]successfully propagated wild measles virus in primary human renal tissue culture cells that a significant understanding of measles was possible. The isolation and propagation of wild measles virus allowed the development of a vaccine, which was licensed for the first time in the United States in 1963. Humans are the only source of measles infection; there is no animal reservoir. Measles is one of the more highly contagious of all infectious diseases and is seen in every country of the world. Before the availability of live measles vaccine, epidemics of measles in temperate climates occurred periodically every 2 to 6 years and lasted approximately 3 to 4 months in late winter and early

spring. In a remote region or on isolated islands, epidemics have longer interepidemic periods of 10 years or more. Epidemics of measles are less marked in equatorial regions. In countries where the live measles vaccine has been used in most of the population, the incidence of measles has decreased by approximately 99 percent.[9,10] In 1993, endemic transmission of measles in the United States was interrupted.[11,12] Subsequent cases in the United States represent imported cases or secondary transmission from imported cases.

The childhood immunization program in the United States has resulted in a greater than 99 percent reduction in reported cases of measles.[4] Since 1965, after widespread use of the measles vaccine (first licensed in 1963), the incidence of the disease has declined in all age groups. A relatively recent (1988 to 1991) recrudescence of measles has been documented; however, the adverse consequences can be associated with suboptimal immunization rates in preschool children, especially in urban areas. Although the major contributing factor to this recurrence of measles was a low immunization rate in preschool-aged children, vaccine failure also played a role (primary vaccine failure occurs in 5 percent of children immunized at 12 months of age). Waning immunity (secondary vaccine failure) may occur, but this did not seem to be a major contributor to the resurgence that began in the late 1980s. Many underdeveloped countries with low immunization rates still have major problems with endemic and epidemic measles.

In 1978, the Department of Health, Education, and Welfare established the elimination of sustained (indigenous) transmission of measles virus in the United States and Canada by 1982 as a formal goal.[4] Although this goal was not achieved, considerable progress was made toward measles elimination from the United States. Before licensure of the measles vaccine in 1963, there was an average of 400,000 measles cases reported each year in the United States. Because nearly all children acquired measles, however, the number was more likely 3.5 million cases per year (i.e., an entire birth cohort).[13] Since the new two-dose measles, mumps, and rubella (MMR) vaccine recommendations were implemented in the United States, imported cases increased from 59 percent of all reported cases in 1997 to 85 percent in 2004.[14,15,16]

From January to July 2008, 131 measles cases were reported to the Centers for Disease Control and Prevention (CDC), whereas from 2000 to 2007, the country averaged 63 cases per year. Although 89 percent were imported from or associated with other countries, particularly Europe, 91 percent of cases were in those who were unvaccinated or of unknown vaccination status.[17] During 2011, 222 cases of measles were reported to the CDC from 30 states—the highest number of reported measles since 1996.[2] The majority (approximately 85 percent) of cases were in people who were unimmunized or had unknown immunization status.[2]

By 1980, the National Childhood Immunization Initiative succeeded in establishing immunization laws requiring administration of many specific vaccines, including measles vaccine, preferably as MMR, before enrollment into public school in most states.[13] Most states have laws requiring the second dose of measles vaccine before enrollment in elementary school or middle school.

Global eradication of measles is feasible, and an eradication program is in progress.[18] The World Health Organization (WHO) and partners in the Measles and Rubella Initiative have developed a Global Measles & Rubella Strategic Plan 2012–2020. The plan presents a five-pronged strategy to cut global measles deaths by at least 95 percent by 2015 compared with 2000 levels and to achieve measles and

rubella elimination in at least five WHO regions by 2020. The strategies include high vaccination coverage; monitoring spread of disease using laboratory-backed surveillance; outbreak preparedness and response and case management; communication and community engagement; and research and development. Between 2000 and 2011, new cases of measles dropped 58 percent from 853,500 in 2000 to 355,000 in 2011.[19]Estimated global coverage with a first dose of vaccine increased from 72 percent in 2000 to 84 percent in 2011. The number of countries providing the second dose through routine services increased from 97 in 2000 to 141 in 2011. Since 2000, with support from the Measles & Rubella Initiative, more than 1 billion children have been reached through mass vaccination campaigns—about 225 million of them in 2011.[20]

Measles virus grows in the cells that line the back of the throat and lungs.[1]Respiratory secretions are the source of virus leading to transmission. Individuals are most contagious during the respiratory (catarrhal) prodromal phase, corresponding to the period from 1 to 2 days before the onset of symptoms (3 to 5 days before the onset of rash) to 4 days after the first appearance of the rash. Measles is transmitted person to person by direct contact with infectious droplets, principally by airborne spread but also by contact. Immunocompromised persons have prolonged excretion of virus from respiratory secretions, and transmission may occur throughout the duration of the symptoms and possibly longer.[4]Asymptomatic contagious carriers do not seem to exist.

Transmission in hospitals and healthcare facility waiting rooms demonstrates a continued need for healthcare facilities to be vigilant and involved with prevention. Healthcare personnel (HCP) should be immune (natural infection or appropriately immunized) and therefore at a decreased risk for acquisition of the disease while working in the healthcare facility.[19]Because some populations may not have access to primary care providers or adhere to appropriate immunization schedules, all patient encounters at healthcare facilities should be used as an opportunity to update immunizations for measles and all other appropriate immunizations for children and adults.

Clinical Manifestations—Measles

Measles has a distinct clinical presentation that allows clinical diagnosis and differentiation from other viral exanthems. Illness usually begins 8 to 12 days after exposure. Respiratory tract symptoms (cough, coryza, and conjunctivitis), fever, and malaise are noted first; these are followed in 2 to 4 days by the characteristic rash. The exanthem begins as an erythematous, macular, or maculopapular eruption. It is usually noted first on the scalp, face, and neck as discrete lesions. These initial lesions enlarge and coalesce as lesions progress to involve the chest, back, and upper extremities. The rash continues to progress with coalescence of lesions on the chest, back, and arms. New discrete lesions may be noted on the abdomen and buttocks. This pattern continues downward on the body with clearing of the initial skin lesions on the face by the time the lower extremities are affected. As the lesions clear, the rash color changes from pink-red to a brawny color, then finally to fine desquamation. Fever is also a prominent sign of measles. The magnitude of the fever parallels the extent of the rash. Koplik spots (enanthem) are present at the end of the prodrome and beginning of the rash. These whitish spots present on the buccal mucosa, typically opposite the molars, are present in 50 to 90 percent of cases, and are pathognomonic for measles. Cough is also present in all cases of measles. When evaluating patients with an erythematous rash, measles should be considered only if the patient has fever, significant cough, and a prodrome including coryza and conjunctivitis.

Of the common childhood exanthems, measles produces the greatest morbidity and mortality. Complications include acute otitis media (superinfection with usual bacterial pathogens), bronchopneumonia (measles giant cell pneumonia and secondary bacterial pneumonia), laryngotracheobronchitis (croup), generalized adenopathy, splenomegaly, and encephalitis.[21]Severe measles and complications (except encephalitis) are more likely to occur in young children (under 2 years of age); individuals who are immunocompromised through malnutrition or have a primary immunodeficiency, particularly cellular immunodeficiencies; and pregnant women.[22,23,24]In immunocompromised populations, the rash may be atypical or not present at all. Encephalitis occurs more commonly in school-aged children.[25,26]Less common complications of measles include keratitis/corneal ulceration, pericarditis, myocarditis, hepatitis, stomatitis, mesenteric lymphadenitis (pseudoappendicitis syndrome), diarrhea, and appendicitis.[27,28]Although the incidence of measles is the same for males and females, complications such as otitis media, laryngitis, and pneumonia are more common in males.[26]Mortality, predominantly due to respiratory tract or neurologic complications, is seen primarily in immunocompromised or malnourished children. Overcrowding and intensive exposure (e.g., household contact or multiple simultaneous contacts) to measles may predispose individuals to more severe complications including death.

Acute measles encephalitis occurs in approximately 1 of every 1,000 cases and can result in permanent brain damage.[4]Subacute sclerosing panencephalitis (SSPE) is a rare degenerative central nervous system complication characterized by behavioral and intellectual deterioration and seizures. It may occur years after measles infection because of the persistence of the measles virus within the central nervous system.

Infection during pregnancy has been associated with more severe illness and an increased risk of miscarriage or preterm delivery. There is no convincing evidence that measles occurring during pregnancy is responsible for congenital malformations.

Milder forms of measles ("modified measles") occur in individuals with some degree of immunity (e.g., children under 6 months of age born to mothers who have had measles or individuals who have received blood products containing measles immunoglobulin [Ig]G antibodies). This illness includes similar clinical findings as typical measles except that the rash and fever are significantly reduced in intensity and duration.

Between 1963 and 1967, a killed measles vaccine was in use in the United States, and the resultant humoral immunity to the vaccine waned within a few years. However, the cell-mediated immunity to measles persisted. After exposure to wild measles, recipients of this killed vaccine developed *atypical*measles, a severe form of measles with a characteristic fever, rash (purpuric rash that may be more prominent on distal extremities), pneumonitis, and hepatitis. The syndrome is hypothesized to result from a hypersensitivity to the measles virus in a partially immune host. The role of humoral or cellular immunity in the pathogenesis of this syndrome is still not elucidated.

The differential diagnoses for patients with a febrile, morbilliform (measles-like rash) presentation include the following:

1. Other viral exanthems (e.g., rubella, roseola, parvovirus B19), differentiated by respiratory tract prodrome, high fever, Koplik spots, and characteristic appearance and progression of the rash

2. Epstein-Barr virus (EBV, mononucleosis), particularly with morbilliform antibiotic drug eruption (e.g., amoxicillin or ampicillin)

3. *Mycoplasma pneumoniae*infection with rash

4. Drug eruption (e.g., phenobarbital, phenytoin, sulfonamides)

5. Kawasaki disease

6. Toxic shock syndrome

Clinical/Laboratory Diagnosis—Measles

A specific diagnosis of measles can usually be made on the basis of clinical presentation alone because of the characteristic prodrome (cough, coryza, and conjunctivitis with or without Koplik spots) and febrile exanthem. As cases of measles become less frequent, however, physicians and other healthcare providers will have less experience with measles infections. These circumstances may diminish the reliability of clinical diagnosis.

Detection of measles virus or antigens in clinical specimens or tissue can establish a recent infection with the measles virus. Viral isolation is possible from respiratory secretions, blood, urine, and, in special circumstances, skin biopsy. Specimens should be collected early in the acute phase of infection to have the greatest likelihood of isolating the measles virus. Specimens should be transported as quickly as possible to the viral laboratory because measles virus is very labile. Transport and storage of specimens is best at 4°C because freezing causes considerable loss of recoverable virus. Virus isolation in cases of measles can be valuable because genotyping assists in the determination of whether the case is endemic or imported. Measles antigen detection in exfoliated cells and tissue can be accomplished using immunofluorescence or polymerase chain reaction (PCR).

Serologic testing may be used to confirm the clinical diagnosis of measles or to assess immunity. The presence of measles IgM antibody by enzyme immunoassay (EIA) confirms a diagnosis of recent measles. Measles-specific IgM antibodies may not be present until 72 hours after the onset of the rash, however. Seroconversion or a fourfold increase in measles IgG antibody titer by EIA, hemagglutination inhibition (HAI), or neutralizing antibodies can also be used to confirm a recent measles infection.

Treatment—Measles

Because measles is generally a self-limited condition in well-nourished, immunocompetent individuals, treatment is usually limited to supportive care that includes the following:

1. Discourage activity during time of fever

2. Encourage adequate hydration

3. Administer agents for fever control (acetaminophen or ibuprofen)

4. Keep room humidified

5. Use antitussives judiciously

Vitamin A has been shown to be valuable for children with vitamin A deficiency. It is recommended for all children with measles who live in communities where vitamin A deficiency is endemic and in geographical locations where the measles case-fatality rate is 1 percent or greater. Although vitamin A deficiency is not a common problem in the United States and other industrialized nations, low serum vitamin A levels have been seen in children with severe measles from these areas. Vitamin A supplementation should be considered in the following individuals:[2]

1. Children 6 months to 2 years old who require hospitalization (e.g., croup, pneumonia, diarrhea)

2. All individuals 6 months old and older with an immunodeficiency or definite or possible vitamin A deficiency (e.g., ophthalmologic evidence of vitamin A deficiency, impaired intestinal absorption, moderate-to-severe malnutrition, or recent immigrant from areas where high mortality rates due to measles have been observed)

The dose of vitamin A is 100,000 international units (IU) orally in infants 6 to 12 months of age and 200,000 IU orally in children 1 year of age and older. Data are limited on safety and need for vitamin A supplementation for infants younger than 6 months. The dose should be repeated 24 hours and 4 weeks after the first dose for children with vitamin A deficiency.

No specific antiviral therapy is available for measles. Ribavirin (aerosol or intravenous) has been given to treat severely affected or immunocompromised children with measles. Efficacy of ribavirin in measles has not been established by clinical trials, however, and it has not been approved for this indication by the U.S. Food and Drug Administration.

Prevention And Infection Control Measures—Measles

The current measles vaccine used in the United States is a live attenuated measles strain prepared in a chick embryo fibroblast cell culture. This vaccine strain, licensed in 1968, is a further attenuated preparation of the Enders-Edmonston strain formerly called Moraten. This strain causes fewer adverse events than the Edmonston B Strain (original live attenuated measles vaccine available in 1963). Measles vaccine is available in a monovalent (measles-only) formulation, combined with rubella vaccine as the MR vaccine, and combined with mumps and rubella vaccines as the MMR vaccine. Measles vaccination of susceptible individuals with the current live-attenuated vaccine causes a mild or clinically inapparent, noncommunicable measles infection. Measles antibodies develop in at least 95 percent of susceptible children vaccinated at age 12 months of age or older.[2]Vaccination of immune individuals is not deleterious. Immunization of individuals whose measles immune status is unknown may be prudent and cost-efficient. Combined MMR vaccine should be given when measles vaccination is indicated if recipients also are likely to be susceptible to mumps or rubella or both.

Serious adverse events after measles vaccine administration are rare. Fever of 39.4°C (103°F) or higher may occur in 5 to 15 percent of susceptible vaccines. The fever is noted 7 to 12 days after receipt of the MMR vaccination and usually lasts 1 to 2 days. Transient rash occurring with the fever occurs in a smaller number of susceptible vaccine recipients (5 percent). Transient thrombocytopenia has rarely occurred temporally associated with administration of measles-containing vaccines. It is more common in individuals with prior thrombocytopenia. Encephalitis and encephalopathy are extremely rare (fewer than 1 per 1 million doses administered) as vaccine-induced neurologic diseases. When seizures occur after measles vaccine, they usually are associated with fever (simple febrile convulsions).

Children with minor illnesses, including those with fever, may be vaccinated with the measles vaccine. The measles vaccine should not be administered during febrile illnesses when there are other manifestations that suggest a serious illness. Children whose measles vaccine is deferred because they have more severe illnesses or other manifestations that suggest a serious illness may be vaccinated shortly after recovery.

Table 86-1 Interval Between Administration of Human-Derived Blood or Immunoglobulin Products and Vaccines Containing Live Rubella or Measles Virus

Indication	Product	Dose (mg IgG/kg)	Route	Interval Between Immune Globulin and Vaccine (mo)
Tetanus prophylaxis	TIG	10	IM	3
Hepatitis A prophylaxis, contact prophylaxis, international travel	IG	3.3 (0.02 mL/kg), 10 (0.06 mL/kg)	IM	3
Hepatitis B prophylaxis	HBIG	10	IM	3
Rabies prophylaxis	HRIG	22 (20 IU/kg)	IM	4
Varicella prophylaxis	VZIG	20–40 (125 U/10 kg) (maximum = 625 U)	IM	5
Measles prophylaxis, nonimmunocompromised contact and immunocompromised contact	IG	40 (0.25 mL/kg) (nonimmunocompromised contact), 80 (0.5 mL/kg) (immunocompromised contact)	IM	5 (nonimmunocompromised contact), 6 (immunocompromised contact)
Blood transfusion				
Washed RBCs		10 mL/kg = negligible IgG	IV	0
RBCs, adenine-saline added		10 mL/kg = 10 mg IgG/kg	IV	3
Packed RBCs		10 mL/kg = 60 mg IgG/kg	IV	6
Whole blood		10 mL/kg = 80–100 mg IgG/kg	IV	6
Platelets		10 mL/kg = 160 mg IgG/kg	IV	7
Plasma products		10 mL/kg = 160 mg IgG/kg	IV	7

RBCs, red blood cells.

Modified from Measles. In: *2012 Red Book: Report of the Committee on Infectious Diseases*, 29th ed. Evanston, IL: American Academy of Pediatrics, 2012; 38.

Measles vaccine is produced in chick embryo cell culture and does not contain significant amounts of egg cross-reacting proteins. Although there is an extremely low risk for an anaphylactic reaction to measles-containing vaccines, persons with severe reactions after egg ingestion should be vaccinated with extreme caution. Skin testing for egg hypersensitivity is not predictive of reactions to the measles vaccine.

Live measles containing vaccines should not be administered to the following individuals:

1. Pregnant women

2. Individuals with significantly altered immunity (primary or secondary immunodeficiency); measles-containing vaccines may be given to human immunodeficiency virus-infected individuals as long as they do not have evidence of current severe immunosuppression at the time of immunization. Severe immunosuppression is defined as CD4+ T-lymphocyte percentages less than 15 percent at any age or a CD4 count less than 200 lymphocytes/mm for persons older than 5 years of age.

3. Individuals who recently received human immunoglobulin or immunoglobulin-containing blood products; individuals who have recently received human blood products need to defer live measles virus vaccine for a time period based on the dose and route of the blood product (Table 86-1).

Certain situations can reduce the protective efficacy of the measles vaccine. Inactivated (killed) measles vaccine is not considered to provide adequate protection and can place recipients at risk for atypical measles. The current measles vaccine in use in the United States is a live vaccine. Improper handling of this live vaccine could result in inactivation of the vaccine with a loss of potency and reduction in immune response. Passively acquired maternal antibodies reduce replication of the measles vaccine virus. Partial immunity to measles at the time of measles vaccine administration causes reduction in antigen production, which results in inadequate levels of measles immune response. In the setting of a measles outbreak, particularly among preschool-aged children, the measles vaccine (monovalent vaccine preferred, but MMR can be given) may be administered to children at risk. Children immunized before their first birthday should be reimmunized at age 12 to 15 months and again before entering school (ages 4 to 6 years).[2]

In addition to maternal measles antibodies, therapeutic administration of blood products that contain measles antibody reduces measles vaccine virus replication and results in suboptimal immune response.[4,29] Table 86-2 describes the interval between human blood product administration and the timing for appropriate administration of measles vaccine.[2]

Table 86-2 Interval Between Administration of Human-Derived Blood or Immunoglobulin Products and Vaccines Containing Live Rubella or Measles Virus

Indication	Product	Dose (mg IgG/kg)	Route	Globulin and Vaccine (mo)
Replacement for humoral immunodeficiencies	IGIV	300–400	IV	8
RSV prophylaxis	RSV-IGIV, palivizumab	750 (RSV-IGIV)	IV, IM	9
Immune thrombocytopenic purpura	IGIV	400, 1000, 1600–2000	IV	8, 10, 11
Kawasaki disease	IGIV	2000	IV	11

RSV, respiratory syncytial virus.

Modified from Watson JC, Hadler SC, Dykewicz CA, et al. Measles, mumps and rubella—vaccine use and strategies for elimination of measles, rubella and congenital rubella syndrome and control of mumps: recommendations of the Advisory Committee on Immunization Practices (ACIP) *MMWR Morb Mortal Wkly Rep.*1998 May 22;47(RR-8):1–57.

Two doses of the measles vaccine are recommended to ensure universal protection. Primary vaccine failure occurs in 5 percent of measles vaccine recipients. The second dose is given to increase the likelihood that this 5 percent who initially did not develop protective antibody levels will subsequently develop immunity.

Healthcare facilities should establish vaccination programs to ensure that all HCP who may be in contact with patients with measles are immune to measles.[4]HCP are at a unique risk for acquiring measles because patients who are ill with measles frequently present for medical care. A lack of familiarity with clinical manifestations of measles enhances the likelihood that HCP will be inadvertently exposed to patients with measles who are not properly isolated.

Measles vaccination during the 72 hours after measles exposure may be protective. Susceptible (nonimmune) HCP, patients, or others who are exposed to a case of measles should be vaccinated as soon as possible, preferably within 72 hours after exposure. Exposure to measles is not a contraindication to immunization with the measles vaccine. If time since exposure has been greater than 72 hours or in certain immunocompromised individuals, however, immunoglobulin may be the preferred method of prophylaxis.

Immunoglobulins[2](immune serum globulin [ISG] or intravenous immunoglobulin [IVIG]) may prevent or modify measles in susceptible persons if given within 6 days of exposure. Susceptible household contacts of patients with measles, particularly infants under 1 year or age, immunocompromised persons, and pregnant women, are candidates for immunoglobulin. The usual recommended dose of ISG is 0.5 mL/kg body weight given intramuscularly. Immunocompromised children should receive 0.5 mL/kg body weight. The maximal dose of ISG is 15 mL. ISG is less expensive and can be given more easily than IVIG. If ISG is in short supply or there is a contraindication to intramuscular injections (e.g., bleeding disorders), IVIG can be administered at a dose of 100 to 400 mg/kg. For patients routinely receiving IVIG (e.g., patients with hypogammaglobulinemia, autoimmune disease), the usual dose of 400 mg/kg should be sufficient for measles prophylaxis for exposures occurring 3 weeks after the most recent IVIG infusion.

RELEVANT INFORMATION FOR MEASLES EXPOSURE EPISODE MANAGEMENT

Measles is a reportable disease in the United States and, depending on the extent of the exposure, the local health department may play a key role in exposure management. Because of the infrequency with which measles is seen at most healthcare facilities, management of measles cases or potential exposure episodes requires an understanding of its clinical presentation, transmission characteristics, populations at risk, and incubation period. Typically, measles has an onset of symptoms 8 to 12 days after exposure (fever, cough, coryza, and conjunctivitis are the initial manifestations—prodrome to rash).[2]The rash usually appears on average 14 days after exposure. The period of contagion begins 1 to 2 days before the onset of overt symptoms (respiratory symptoms, not rash) and continues until 4 days

after development of the rash. The duration of viral excretion (transmissibility) is prolonged for at least the duration of illness in immunocompromised individuals. Measles does not occur in individuals with prior immunity to measles. Criteria that may be used to determine immune status of individuals include the following:

• Lab evidence of immunity

• Documention of age appropriate vaccination with a live measles virus containing vaccine

• Lab confirmation of disease. Physician diagnosed history of measles is no longer considered an acceptable criterion of evidence of immunity.[29]

Documentation of adequate vaccination requires written verification of the receipt of two doses of measles vaccine on or after the first birthday because vaccine given before the first birthday cannot be considered to satisfy the two-dose requirement. Reliability of a physician-diagnosed history of measles depends on epidemiologic factors and the experience of the physician. In addition, most persons born before 1957 were infected naturally and should be considered immune.[30]Individuals born before 1957 without a history of measles should be screened serologically for immunity.

Measles is highly contagious and is spread by large and small droplets. Susceptible patients who have been exposed to an individual with measles (contagious) should be placed in an airborne infection isolation room from the fifth to the twenty-first day after exposure (regardless of whether they received measles vaccine or immunoglobulin for this specific exposure) or from the onset of symptoms until 4 days after the onset of the rash if the patient becomes ill.[2,27]Susceptible HCP who have been exposed to an individual with measles should be furloughed (relieved from healthcare activities) from the fifth to the twenty-first day after exposure, regardless of whether they received measles vaccine or immunoglobulin after exposure or until 4 days after development of their rash. HCP who develop measles should be furloughed until they have had their rash for 4 days. Susceptible patients and personnel may be given a live attenuated measles-containing vaccine within 72 hours of exposure to modify disease. This vaccine does not modify the need for isolation precautions or furlough. Susceptible patients and HCP who are immunocompromised should be given immunoglobulin to modify their disease (as described previously). Immunoglobulin does not modify the need for isolation or furlough.

Airborne infection isolation requires a single (private) room with negative pressure ventilation, adequate air exchanges per hour, and direct exhaust to the outside environment or recirculated through a high-efficiency particulate air filter before returning to circulation; susceptible persons should not enter the isolation room.[2,31]Mask, gowns, and gloves are not essential, but HCP should follow Standard Precautions.[31]For patients with proven or suspected measles, airborne infection isolation should start with the onset of symptoms (respiratory tract or rash) and be maintained until 4 days after the appearance of the rash. Patients with documented or suspected SSPE, atypical measles, and measles vaccine–induced fever or rash do not require any form of isolation.[2]

Conclusions—Measles

Measles remains an important infection worldwide, and the availability of an effective vaccine has significantly reduced cases. Endemic measles essentially has been eliminated in the United States, but the ease of global travel still allows imported measles cases. Until global elimination of measles is a

reality, healthcare providers should be aware of the clinical manifestations of measles, means of diagnosis, and methods to limit transmission. Healthcare facilities should ensure adequate immunity of HCP, such as through use of the live measles vaccination, appropriate environmental controls, (negative airflow isolation rooms), and exposure management guidelines and policies.

Future Trends—Measles

The goal is to maintain measles elimination efforts in the United States through rapid and efficient public health response resulting in limited outbreak size, especially in communities with subpopulations who choose not to vaccinate their children.[32]

International Perspective—Measles

Despite an effective vaccine, measles still results in considerable morbidity and mortality in many areas of the world. The impact of measles is greatest in children, especially those who are malnourished or have immunodeficiency conditions (primary or acquired). The Measles and Rubella Initiative's goal is now to reduce measles deaths worldwide by 95 percent by 2015 and to eliminate measles and rubella in at least five of six WHO regions by 2020.[20]

Abstract—Mumps

Mumps is a systemic, commonly self-limited, viral infection caused by an enveloped ribonucleic acid virus belonging to the genus *Rubulavirus*, which is a member of the Paramyxoviridae family. Clinical infection is characterized by swollen salivary glands (parotitis), high fever, and fatigue. Parotitis, when present, is usually bilateral and is observed in 30 to 40 percent of those infected. Humans are the only natural host. Transmission occurs through droplets of respiratory secretions. Communicability is comparable to influenza and rubella, less than that of varicella or measles, and is maximal from 2 days before onset of parotitis to 9 days after. The average incubation period for mumps is 18 days, with a range of 12 to 25 days. After licensure of a vaccine against this virus, the incidence has decreased dramatically. For example, in 1989 there were more than 5,700 cases reported compared with 231 cases in 2001. Most cases occur in children aged between 5 and 14 years; however, outbreaks can still be seen even when immunization levels are high. In 2006, the United States experienced the largest mumps outbreak in two decades, affecting primarily college students aged 18 to 24 years.

Key Concepts—Mumps

• Since 1989, there has been a steady decline in reported mumps cases, most likely as a result of implementation of the second-dose recommendation for measles vaccine (as MMR vaccine).

• The most important intervention to keep incidence low is to ensure that susceptible persons, including healthcare personnel, receive two doses of MMR.

• Outbreaks have been common whenever large groups of individuals are in close contact or a significant number of susceptible persons are gathered, such as in schools, military settings, prisons, ships, and remote islands.

• Humans are the only known natural host of mumps virus.

• Transmission is by droplet spread of respiratory secretions, through direct contact with infected fluids (primarily saliva or urine), and occasionally via fomites.

• Supportive measures and use of analgesic-antipyretics for pain and fever are typical measures for those with disease, with attention to adequate hydration.

• Droplet Precautions are recommended for people with acute mumps infection for 9 days after onset of parotid swelling. Susceptible healthcare personnel should not care for such patients; use immune personnel instead.[31]

Background—Mumps

The mumps virus, included in the genus *Rubulavirus*and within the family Paramyxoviridae (includes parainfluenza and Newcastle disease virus), causes mumps. The name "mumps" likely came from an old English verb for "grimace, grin, or mumble."[33]This single-stranded ribonucleic acid (RNA), lipid-enveloped virus was established as the etiologic agent of mumps in 1934,[34]and subsequently a vaccine incorporating an attenuated form was prepared by Buynak and Hilleman in 1966.[35]Mumps infection, though systemic, is usually self-limited with symptoms of unilateral or bilateral parotitis, high fever, and fatigue. Most cases are seen in children and adolescents between the ages of 5 and 19 years.

Historically, outbreaks of mumps were common among military personnel, and the incidence of this disease was third behind influenza and gonorrhea as a cause of hospitalization among soldiers during World War I. An estimated 212,000 cases occurred in the United States in 1964, and starting in 1968, mumps became a nationally reportable disease. With the development and implementation of an effective vaccine, incidence decreased rapidly to approximately 3,000 cases per year. However, beginning in 1986, there was a resurgence of mumps with a peak in 1987 of 12,848 reported cases, primarily among adolescents and college-age adults who were born before consistent requirement for mumps vaccine in children. Outbreaks have occurred in healthcare facilities as well, primarily a reflection of birth cohort-related susceptibility.

Since 1989, there has been a steady decline in reported mumps cases, from 5,712 cases to a provisional total of 231 cases in 2001, the lowest annual total ever reported. The decrease in mumps in recent years is most likely the result of implementation of the second dose recommendation for measles vaccine (as MMR vaccine). Primary prevention by ensuring susceptible persons receive two doses of MMR is the most important intervention to keep incidence of this viral disease as low as possible.

More recently, in 2006, an outbreak of mumps resulted in reports of 2,597 cases of mumps in 11 states in the United States. From 2009 through 2010, mumps outbreaks occurred in a religious community in the Northeastern United States, with approximately 3,500 cases.[36]In 2011, a university campus in California reported 29 cases of mumps, of which 22 (76 percent) occurred among persons previously vaccinated with the recommended two doses of MMR vaccine.[36]The age group most affected was young adults aged 18 to 24 years; most were college students, but the disease spread to all age groups. Subsequently, the Advisory Committee on Immunization Practices (ACIP) updated the recommendations for mumps vaccination.

Basic Principles—Mumps

VIROLOGY

The surface proteins on the mumps virion (virus) perform two functions: hemagglutination-neuraminidase activity and cell fusion. During the 18-day incubation period, the virus multiplies in the upper respiratory tract tissue after infection of T lymphocytes. Lymph nodes are the focal point for viral replication, and viremia allows dissemination throughout the body.[37](Also refer to **22. Microbial Pathogenicity and Host Response**, for more information on T lymphocytes and immunity.)

PATHOGENESIS

The virus is acquired by respiratory droplets and subsequently replicates in the nasopharynx and regional lymph nodes. After 12 to 25 days, a viremia occurs that lasts from 3 to 5 days. During the viremia, the virus spreads to multiple tissues, including the meninges, and glands such as the salivary, pancreas, testes, and ovaries. Inflammation in infected tissues leads to characteristic symptoms of parotitis and, in up to 10 percent of cases, aseptic meningitis.

IMMUNE RESPONSE AND PRIMARY PREVENTION

After infection, both cell-mediated and humoral-mediated immune responses develop. The latter produces virus-specific antibody, which appears to be key to resolution of initial infection. The stimulation of immune response through use of mumps virus vaccine has resulted in a notable decline in the incidence of mumps and its associated complications. Primary prevention (i.e., use of live-attenuated vaccine) is very effective as evidenced by dramatic declines in wild virus infections. The vaccine used in the United States is composed of the Jeryl Lynn B strain of mumps that is attenuated through a series of passages via cell cultures. Another strain, the Urabe Am^9used in Japan, Europe, Canada, and other countries since 1979 to the early 1990s, was withdrawn because of an observed adverse event involving vaccine-virus meningitis that appeared within 4 weeks after receipt.[38,39,40]A third vaccine formulation using the Rubini strain used in some countries does not appear to be as effective in eliciting immune response.[41]

Neutralizing antibody is evident by approximately 2 weeks after immunization, with more than 97 percent of recipients developing evidence of immune response after a single dose. Mumps-specific neutralizing antibody persists for more than 25 years, and immunity probably is lifelong. Clinical efficacy of the vaccine in preventing disease ranges from 90 to 97 percent.

Epidemiology—Mumps

DISEASE TRENDS

Before licensing of the mumps vaccine in the 1960s, more than 200,000 cases of mumps occurred each year, often in epidemic levels every 2 to 5 years, predominantly among young children.[42]In 1977, the U.S. Public Health Service recommended universal vaccination against mumps for children 12 months of age and older.[43]Revised recommendations released in 1980 to include susceptible children, adolescents, and adults have, in combination with laws requiring mumps vaccination for school entry, resulted in a steady decline in incidence (e.g., 2 per 100,000 population in 1988 to 0.7 per 100,000 population in

1993).[43]Figure 86-1 illustrates this declining incidence since provision of mumps vaccine on a national basis. Comprehensive school immunization laws, routine vaccination of young children, and policies targeting older populations of susceptible persons have all contributed to the decline in incidence of mumps. For example, reported incidence rate of mumps in states with legal requirements for vaccination before entry to school were 1.3 cases per 100,000 population versus 2.9 cases per 100,000 population for states without such requirements.[43]States in which vaccination laws were less comprehensive reported intermediate mumps incidence, with the highest incidence reported in states without such laws.[44]

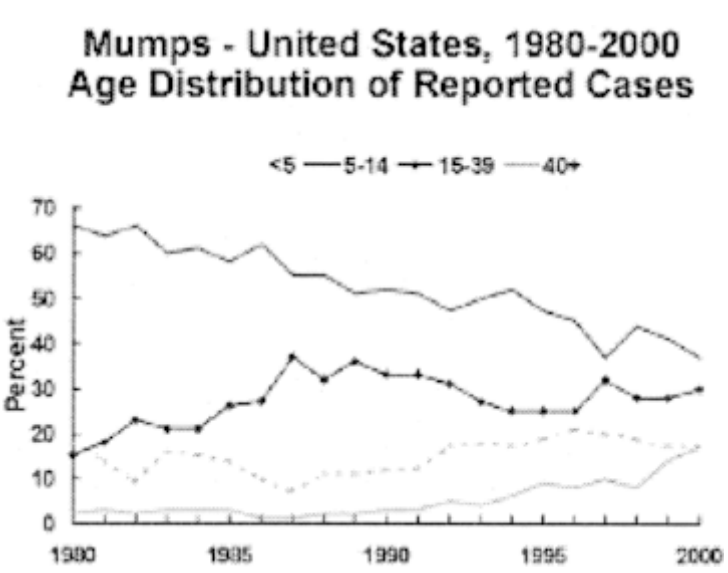
View Image



Administration of the mumps vaccine has resulted in a 99 percent decline in the incidence of mumps in the United States.[43]Before vaccine licensure in 1967 and during the early years of vaccine use, most reported cases occurred in the 5- to 9-year age group; 90 percent of cases occurred among children under 15 years of age. As illustrated in Figure 86-2, in the late 1980s there was a shift in greater incidence of disease among older children. The peak number of cases in the United States in 1987 (12,848) primarily affected those aged 10 to 19 years, who were born before implementation of routine vaccination and school entry immunization requirements. Since 1990, persons aged 15 years and older have accounted for 30 to 40 percent of cases per year. Males and females are affected equally. Seroepidemiologic studies in other countries have identified a low incidence of mumps where vaccine coverage is high; low vaccine use results in susceptible populations, especially among adolescents and young adults.[45]

Age distribution of reported cases of mumps, United States, 1980–2000. Source: CDC.

View Image

Outbreaks have been common whenever large groups of individuals are in close contact or a significant number of susceptible persons are gathered, such as in schools, military settings, prisons, ships, and remote islands.[43,46,47,48]A report by Kaplan et al.[49]on an outbreak of mumps among employees at three Chicago futures exchanges reflects the change in populations at risk. A total of 119 cases were observed among employees and their contacts, and 77 percent of these were in persons younger than 30 years (median 5 to 25 years). Cost of control for this outbreak was approximately $1,500 per case

(compared with the cost of mumps vaccine of $4 to $9 in 1988 dollars), and almost none of the cases could produce written documentation of receipt of mumps vaccine.

MODE OF TRANSMISSION, INFECTIVITY, AND INCUBATION PERIOD

Humans are the only known natural host of mumps virus. Transmission is by droplet spread of respiratory secretions, via direct contact with infected fluids (primarily saliva or urine), and occasionally via fomites. The virus attaches to epithelial cells of the respiratory tract and replicates. The period of communicability begins 1 to 2 days (but can be up to 7 days) before onset of symptoms (e.g., parotid swelling) through 9 days thereafter.[50]Risk of transmission to a susceptible person is highest over the 7-day period beginning 2 days before parotitis. Those with relatively few or no symptoms can transmit the disease, and 30 to 40 percent of infections are subclinical. The incubation period ranges from 12 to 25 days (usually 16 to 18 days). Infectivity is greatest just before parotid swelling.

Treatment—Mumps

Supportive measures and use of analgesic-antipyretics for pain and fever are typical measures for those with disease. Attention to adequate hydration is important.

Prevention And Infection Control Measures—Mumps

PREVENTION AND CONTROL OF MUMPS WITHIN HEALTHCARE FACILITIES

Transmission of mumps within hospitals and long-term care facilities housing adolescents and young adults has been reported.[51,52,53,54,55]Although Droplet Precautions are recommended for people with acute mumps infection, use of Isolation Precautions for persons with infection has not been shown to be very effective.[56,57]This probably reflects the fact that the virus is shed before onset of clinical disease, and asymptomatic cases can also transmit infection. Transmission in hospitals in Tennessee has been studied by Wharton et al.[54]Most cases examined were community acquired; however, six healthcare personnel (HCP) in three different institutions and nine patients in a long-term care setting for adolescents and adults were infected after exposure in the healthcare setting.

Fischer et al.,[55]while acknowledging that mumps vaccine has not been demonstrated to be effective in preventing infection postexposure, suggests that it may prevent tertiary cases when administered soon after diagnosis of the index case.[55]Two of 149 exposed employees (one with an inaccurate history of mumps in childhood) and 1 of 29 exposed patients developed an infection from a 12-year-old foreign-born girl in this report.[55]Total expenditures for control of this outbreak were $3,140, which reinforces the

value of ensuring that two doses of MMR are given to susceptible HCP regardless of birth year; one case in this report occurred in an individual born before 1957.

Exposed HCP may be infectious for 12 to 25 days after their exposure. Recommendations for control and prevention of mumps in healthcare settings include (1) administering vaccine (preferably MMR) to all who are not immune, unless otherwise contraindicated; (2) restricting susceptible HCP from care of patients with acute mumps, and, when feasible, using immune personnel instead; and (3) excluding susceptible personnel after exposure from duty from the twelfth day after the first exposure to the twenty-sixth day after the last exposure or, if symptoms develop, until 9 days after the onset of parotitis.[58] Passive antibody administered after exposure is not effective in preventing disease. Transmission of mumps from HCP to patients has not been a major problem in hospitals in the United States, reflecting high levels of natural and vaccine-induced immunity in the general population. Droplet Precautions (i.e., placement in a private room if possible and use of a mask by HCP when working within 6 feet of the patient infected with mumps until 9 days after onset of parotid swelling) are recommended.[31,56]

PRIMARY PREVENTION USING MUMPS VACCINE

The principal strategy to prevent mumps is to achieve and maintain high immunization levels, primarily in infants and young children through vaccination programs with two doses of MMR vaccine.[59] In addition, all others thought to be susceptible should be vaccinated unless otherwise contraindicated.[59]

The mumps vaccine virus cannot be transmitted to other persons.

Two doses of mumps vaccine, as combination MMR vaccine, separated by at least 4 weeks, are routinely recommended for all children. The first dose should be given on or after the first birthday. The second dose should be given between the ages of 4 and 6 years, preferably before entering kindergarten or first grade. If not, the second dose should be given during a subsequent health visit between the ages of 11 and 12 years. All persons born in or after 1957 should have documentation of at least one dose of MMR.

Although birth before 1957 is generally acceptable evidence of immunity against MMR, healthcare facilities should consider recommending a dose of MMR vaccine to unvaccinated workers born before 1957 who do not have a history of physician-diagnosed or laboratory evidence of immunity.[58,60]

Recommendations for use of mumps vaccine for preschool-aged children through adolescents, women of childbearing age, those with underlying human immunodeficiency virus (HIV) infection, and those in colleges/post–high school educational institutions are available elsewhere.[50,61] Recipients of a killed mumps vaccine or one of unknown type, available between 1950 and 1978, should be revaccinated with MMR if at high risk for mumps infection (e.g., HCP). Immunity from this killed vaccine was transient, and the vaccine was administered rarely after licensure of the live-attenuated vaccine in 1967.

During a mumps outbreak, a second dose of mumps vaccine should be considered for children aged 1 to 4 years and adults who have received one dose. In healthcare settings, an effective routine MMR vaccination program for HCP is the best approach to prevent nosocomial transmission. It is recommended that healthcare facilities strongly consider administering two doses of a live mumps virus vaccine to unvaccinated HCP born before 1957 who do not have evidence of mumps immunity.

Because immunoglobulin may interfere with response to MMR vaccine, it should not be given for 5 to 6 months or more after administration of vaccine. The type of antibody-containing immunoglobulin product and clinical circumstances may preclude this spacing interval. Primary vaccination failures among

populations with high vaccination use have been reported.[62,63,64,65] Current recommendations for a second dose of MMR vaccine between ages 4 and 6 years can reduce vaccine failures. Efficacy has also been diminished because of an alteration in the specific strain of virus used in vaccine preparation, resulting in outbreaks of disease.[65] Information on adverse reactions after MMR vaccination, precautions, and contraindications has been published.[33,66] MMR vaccine may interfere with response to a tuberculin skin test (TST). Therefore, TST can be performed either on the same day MMR vaccine is given or 4 to 6 weeks later.

In the United States, each state and territory has regulations or laws governing the reporting of diseases and conditions of public health importance. Probable or confirmed cases should be reported immediately to the local and state health departments and contacts identified; follow-up serologic testing, when indicated, should be accomplished.

Steps involved in control of outbreaks of mumps in healthcare settings include:

1. Definition of target population

2. Identification of susceptible persons needing vaccination

3. Exclusion of susceptible HCP who are exempt from vaccination (e.g., medical or religious reasons) from the affected institution or setting until the outbreak is terminated

4. Active surveillance for mumps until two incubation periods (i.e., 5 to 6 weeks) have elapsed since onset of the last case.[50,60]

Mumps is less transmissible than measles and other microorganisms spread via the airborne or droplet routes. A high level of immunity among HCP through provision of vaccine is the most effective method for preventing spread in healthcare settings. Risk for transmission in a healthcare facility is low because it generally reflects incidence within the surrounding community or population served.

Although mumps vaccination has not been shown to be effective in preventing mumps in persons already infected, it will prevent infection in persons who are not infected. If susceptible persons can be vaccinated early in the course of an outbreak, they can be protected. However, cases are expected to continue to occur among newly vaccinated persons who are already infected for at least 3 weeks after vaccination because of the long incubation period. As with all vaccines, there are some individuals who will not gain immunity after receipt of mumps vaccine. Because vaccine effectiveness is not 100 percent, a second dose of mumps-containing vaccine is recommended during outbreak situations for individuals who have received only one dose previously. Studies have shown a trend toward a lower attack rate among children who have received two doses of mumps vaccine as opposed to those who have received one dose.[33] Furthermore, birth before 1957 does not guarantee mumps immunity, and in outbreak settings vaccination with a mumps-containing vaccine should be considered for those born before 1957 who may be exposed to mumps and may be susceptible.[62,63,64,65]

The MMR vaccine is very safe, and the most common adverse events associated with vaccination include pain at the site of vaccination and induration. The frequency of more severe events, such as anaphylaxis or allergic reaction, is 1.6 per 100,000 doses.[66,67,68] Concerns about association between MMR and autism have prompted scrutiny of this possible link by several consumer advocacy groups. An extensive study of 537,303 children found strong evidence against any causal link between MMR

vaccine and autism. In addition, 10 of 12 authors of a study of a small number of patients that stated a possible association between MMR and autism have retracted this interpretation. Periodic resurgence of such concerns may undermine confidence or create lingering doubt about the safety of vaccines; however, these misconceptions need to be countered with scientific evidence and strategies to reinforce the lifesaving benefits of immunization.[69]The alternative to decreased immunity among populations will be a resurgence of disease and greater burden of associated morbidity, mortality, and costs on society as a whole.

FINANCIAL AND COST-EFFECTIVENESS ANALYSIS

Primary prevention against mumps for HCP mitigates disease-associated morbidity, expenditure of time and effort for control measures, and disruption of healthcare delivery associated with transmission in healthcare settings and the community. Immunization of susceptible persons has been shown to be cost-effective, with a ratio of $1 in vaccine cost to between $7 and $14 in disease-associated expense.[70,71]

Conclusions—Mumps

Mumps is an infrequent cause of infection in both the community and within healthcare facilities in the United States. When infection does occur, it is most often a self-limited viral illness characterized by parotitis. Prior experience has demonstrated that transmission of infection can occur even in populations with a relatively high proportion of immunized persons. The mumps vaccine has been a notable success in preventing infection, as evidenced by a decrease of more than 200,000 cases per year before its implementation to a low of just more than 200 cases in 2001 in the United States. To sustain this success, continual attention to ensuring that vaccine is provided to susceptible persons as part of an organized immunization program is critical.

Infection prevention failures resulting in healthcare-associated transmission have occurred in outbreaks involving healthcare facilities that admitted adolescents and young adults. Review of isolation procedures, HCP immune status, and provision of appropriate vaccination should be considered.

Future Trends—Mumps

Compromised confidence in efficacy of vaccines is a constant threat to resurgence of diseases that are preventable. HCP must keep current with ongoing research involving vaccines and advocate for their use as one of the most cost-effective interventions to improve health. Surveys of HCP, however, have found unfamiliarity with national immunization schedules for susceptible populations (i.e., ensuring two doses of MMR) and incorrect association between vaccine and adverse events.[72,73]Such weaknesses pose a threat to resurgence of vaccine-preventable diseases. Despite ample scientific investigation of adverse events and improvement in the delivery of vaccine, in 2001, only 77.2 percent of U.S. toddlers aged 19 to 35 months had received recommended immunizations.[74]Healthcare providers at all levels, therefore, will need to be advocates for and facilitate provision of vaccines at all healthcare encounters.

International Perspective—Mumps

The World Health Organization (WHO) reports an average annual incidence of mumps in many parts of the world of between 100 and 1,000 per 100,000 population with epidemic peaks noted every 2 to 5 years—especially when no national vaccination initiative is present (e.g., Southeast Asia and select countries in Africa).[75]Approximately 120 countries have incorporated mumps vaccine into their national immunization programs, and after widespread immunization, incidence of disease decreases dramatically. The WHO recommends use of mumps vaccine in countries with efficient national vaccination programs and sufficient resources to sustain such a program.

A seroprevalence survey in Japan revealed that 15.9 percent of more than 270 newly hired HCP lacked evidence of antibody against mumps virus, and a subsequent vaccination program was determined as cost effective.[76]Another survey among hospitals in New South Wales, Australia, found that only 14 percent of hospitals provide MMR immunization and that susceptibility to measles and other viral infections ranges between 14 and 28 percent.[77]To prevent transmission of mumps in the general population and healthcare facilities, greater attention must be paid to assessment and provision of vaccine.

Abstract—Rubella (German Measles)

Rubella was first described in the German literature in the early part of the nineteenth century. Since that time, rubella has been clearly defined as a mild, self-limited viral exanthem with a potential to cause serious disease in the fetus. Isolation of the virus in 1962 was the first step in the development of a live-attenuated vaccine. The timing of the first isolation was remarkable because it shortly predated one of the most devastating worldwide pandemics of rubella in 1964 and 1965. In the United States alone, there were more than 12 million cases of rubella with greater than 20,000 cases of the congenital rubella syndrome (2,100 neonatal deaths). The licensure of the first rubella vaccine in 1969, with subsequent improvements in the vaccine (RA 27/3 licensed in 1979), has resulted in dramatic reductions in rubella cases and congenital rubella syndrome in the United States (23 cases of rubella and two cases of congenital rubella syndrome in 2001) and in other countries with successful rubella immunization programs. Unfortunately, many developing nations have yet to benefit from the rubella vaccine, where resources are not available to allow universal routine rubella immunizations. In 2003, only seven confirmed cases of rubella were reported in six states in the United States. The majority of these cases occurred in those aged more than 20 years.

Key Concepts—Rubella

• There is mild acute exanthematous infection of children and adults.

• Greatest health risk is associated with fetal infection (acute clinical manifestations, birth defects, and long-term sequelae) acquired after maternal infection in the first trimester of pregnancy.

• Live-virus vaccine has markedly reduced rubella infections and perinatal consequences in countries with successful rubella immunization programs.

Background—Rubella

Rubella virus, first isolated in 1962 by Parkman and Weller, is in the genus *Rubivirus*in the Togaviridae family. It has a single positive-stranded ribonucleic acid (RNA) genome, an icosahedral capsid, and a lipoprotein envelope. The name "rubella" comes from the Latin for "little red." It was previously called "third disease" and was thought to be a mild variant of measles or scarlet fever. Humans are the only natural hosts for rubella. However, under experimental conditions, a wide range of vertebrate species may be infected with the rubella virus. Rubella virus is labile and readily inactivated by several chemical agents (e.g., chlorine, formalin, trypsin, deoxycholate), lipid solvents, heat (greater than 56°C), cold (less than –10°C to –20°C), ultraviolet light, and extremes of pH (less than 6.8 and greater than 8.1).[78,79,80]

Basic Principles—Rubella

There are two distinct genotypes of rubella virus differentiated by nucleotide sequences that code for structural proteins.[78,79]However, only minor immunologic differences exist between the two genotypes, and immunity to one rubella virus provides protection against all other rubella viruses (one antigenic type).[80]Humans are the only natural hosts of the rubella virus.

Rubella infection of nonpregnant individuals results in a benign, self-limited illness. Although there is a characteristic presentation for acquired rubella (an exanthem and lymphadenopathy), many infections with rubella are asymptomatic. Of greater consequence is *in utero*infection, which results in the congenital rubella syndrome (intrauterine growth retardation, mental retardation, congenital heart disease, deafness, and numerous ocular abnormalities).

Infection with the rubella virus commences in the respiratory epithelium of the nasopharynx. The virus spreads rapidly from the nasopharynx to regional lymphatics. Viremia follows lymphatic involvement (approximately 5 to 7 days after exposure), occurs 1 to 2 days before the onset of rash, and peaks just before the onset of the rash. Viremia is not detectable soon after the onset of rash. However, rubella virus replication continues in the nasopharynx for up to 6 to 14 days after the appearance of the rash. Transplacental passage of the virus may occur as a result of viremia or after placental infection.

Epidemiology—Rubella

The availability of a safe, live-virus rubella vaccine has resulted in dramatic declines in both acquired rubella infections and the congenital rubella syndrome in populations with effective rubella vaccine programs. Occasional rubella outbreaks in unvaccinated populations continue to occur in the United States. However, these are becoming less common and do not appear to spread even in under-vaccinated populations, likely because of effective herd immunity.[80,81,82,83,84,85,86]

Humans are the only known vertebrate host and only source of rubella. Postnatally acquired rubella is transmitted chiefly through direct or droplet contact. The virus is shed primarily in respiratory secretions (nasopharyngeal and to a lesser degree oropharyngeal), allowing transmission via direct contact and to a lesser degree via droplet transmission.[81]Efficient transmission to susceptible persons requires prolonged and intimate contact. Individuals infected with rubella are contagious from a few days before the onset of symptoms (7 days before rash) to 7 to 14 days after the rash. Children with congenital rubella shed virus from both respiratory secretions and urine. Children with congenital rubella should be

considered to be contagious until 1 year or more of age, unless they have had repeated negative virus cultures of the nasopharynx and urine.

Before the widespread use of rubella vaccine, rubella was an epidemic disease occurring in 6- to 9-year cycles. Most clinically identified cases occurred in school-aged and preschool-aged children. The peak incidence of rubella infection in the prevaccine era was in the late winter and early spring. However, in areas with low levels of vaccine use, an endemic level of rubella transmission occurs year-round. Immunity after infection is usually lifelong and durable. However, reinfection has been documented on rare occasions and has even resulted in transmission of rubella virus to the fetus with a resulting congenital rubella syndrome.[87,88]

Since the availability of a rubella vaccine in 1969, widespread rubella outbreaks have been prevented. This reduction in rubella transmission occurred despite high proportions of selected populations remaining susceptible (no natural infection and no vaccine). Most persons born after 1969, and many born between 1964, the year of the last major worldwide rubella epidemic, and 1969, who were not vaccinated (i.e., approximately 20 percent of the population) are not rubella immune. Therefore, this reduction in rubella transmission presumably reflects the influence of "herd immunity."

The National Childhood Immunization Initiative succeeded in establishing laws requiring rubella vaccination before entering public school in most states in the United States by 1980. Consequently, the majority of unprotected individuals in the United States were born between 1964 and 1975. Some of these susceptible individuals may have been reached after the new two-dose schedule recommendation for measles (many received MMR vaccine) and when secondary and undergraduate/graduate schools began requesting/requiring proof of rubella immunity for enrollment.

Surveillance data for rubella and congenital rubella continue to show a steady decline in reported cases to record low levels. Reported cases of postnatal rubella declined to a low of 23 cases in 2001.[89] In 1995 and 1996, there were only four and two confirmed cases, respectively, of congenital rubella syndrome reported in the United States.[85] In 2001, there were two cases of congenital rubella syndrome among 11 women with rubella infection during their pregnancy; of these, 10 mothers were foreign-born Hispanics.[89]

During the 1970s, the age spectrum of reported rubella shifted gradually toward older individuals. In 1979, 36 percent of rubella cases were among persons older than 20 years of age. The first shift toward cases in older patients presumably reflected the initial emphasis on vaccinating infants and schoolchildren. However, by 1981, the age spectrum once again shifted sharply toward younger cases. In 1981, only 24 percent of cases were among persons older than 20 years of age.[85] The second shift toward cases in younger patients represented a decrease in susceptible adults, because those vaccinated as schoolchildren were entering adulthood, plus an increase in efforts to identify the remaining susceptible adolescents and young adults, particularly during prenatal care. These more recent cases of rubella were occurring in unvaccinated children (as was the case for measles during the measles resurgence in 1988 to 1991). More recently from 1992 to 2000, there has been another shift with an increase in the proportion of cases in older individuals, primarily between the ages of 15 and 39 years. However, the significance of this shift is not clear because of the relatively small number of total cases of reported rubella. In 2000, 87 percent of rubella cases occurred in persons 15 to 39 years of age. In 2003, seven confirmed cases were reported in six states, the lowest number of rubella cases ever reported in the United States.

Because there is no animal reservoir for rubella, elimination of indigenous transmission of rubella in the United States (and possibly the world) is feasible.[84] Because rubella is transmitted less readily than measles, sustained (indigenous) transmission should be easy to eliminate. On the other hand, rubella is less clinically distinctive, so imported cases are harder to recognize and control. In 2010, on the basis of surveillance data, the Pan American Health Organization indicated that the World Health Organization (WHO) Region of the Americas had achieved the rubella and congenital rubella syndrome elimination goals set in 2003.[84] Verification of maintenance of rubella elimination in the region is ongoing. However, an expert panel reviewed available data and unanimously agreed in December 2011 that rubella elimination has been maintained in the United States.[59,90]

Clinical Manifestations—Rubella

Postnatal rubella or German measles is generally a mild, viral exanthem with little risk for morbidity or mortality. After an incubation period of 14 days (range 12 to 23 days), postnatal illness begins with a prodrome consisting of malaise, headache, low-grade fever, mild conjunctivitis, and lymphadenopathy. This prodrome may be so mild as to go unnoticed. The rash follows the prodrome or at times it may be the first symptom noted in children and adults. Respiratory tract symptoms, constitutional symptoms, and rash are quite variable in presentation (25 to 50 percent of individuals infected with rubella are asymptomatic). Not all ill patients with an acute rubella infection have a discernible rash. Rubella should be suspected in susceptible individuals who develop a fine maculopapular rash and lymphadenopathy after a possible rubella exposure. Compared with the rash of measles, the rash in patients with rubella is usually less intense in color, more variable in its presentation, and of shorter duration (3 days for rubella; 5–7 days for measles). It has both scarlatiniform and morbilliform characteristics. Arthritis or arthralgia or both occur in up to one-third of adolescent and adult women infected with rubella. Thrombocytopenia, encephalitis, neuritis, and orchitis rarely occur.

Rubella virus may be transmitted to the fetus after viremia or placental infection during the entire gestation period. However, the risk for fetal damage and sequelae is primarily seen after transmission occurring in early gestation. The risk for the congenital rubella syndrome by gestational age is as follows: first month, 45 percent; second month, 25 percent; third month, 15 percent; fourth month, 10 percent; and minimal risk during all later months. Rubella infection in a susceptible mother after the twelfth week of gestation is not likely to cause adverse consequences to either the fetus or the mother. Children who are born with congenital rubella syndrome may exhibit some or many of the following conditions: intrauterine growth retardation, petechiae/purpura, mental retardation, anemia, hepatosplenomegaly, congenital heart defects (particularly patent ductus arteriosus and peripheral pulmonary stenosis), radiolucent bone disease, cataracts, glaucoma, retinitis, failure to thrive, and occasionally postnatal death. In addition to the congenital rubella syndrome, early gestation infection rubella has been associated with an increased rate of miscarriages and stillbirths.

Clinical/Laboratory Diagnosis—Rubella

Because most rubella infections are asymptomatic or associated with mild nonspecific symptoms, diagnosis of rubella based on clinical findings alone is difficult, particularly in nonepidemic periods or locations. The rash has characteristics of both scarlet fever (scarlatiniform) and measles (morbilliform) and may be confused with mild cases of either of these infections. In addition to measles and scarlet fever, other infections with presentations that at times may be similar to rubella include infectious

mononucleosis due to the Epstein-Barr virus (EBV), cytomegalovirus (CMV) or toxoplasma maternal infections, roseola infantum (human herpesvirus 6 [HHV-6] and human herpesvirus 7 [HHV-7]), erythema infectiosum (parvovirus B-19), and many of the enteroviral infections. (Also see **41. Neonates**, **42. Pediatrics**, **43. Perinatal Care**, **80. Herpes Virus**, and **88. Parvovirus**.)

Infants with congenital rubella may present with clinical manifestations that may be indistinguishable from perinatally acquired CMV and toxoplasmosis. Thrombocytopenia, petechiae/purpura, anemia, hepatomegaly, splenomegaly, retinopathies, bone abnormalities, eighth nerve deafness, and intrauterine growth retardation may be seen with congenital infections with rubella, CMV, or toxoplasmosis. Congenital heart defects, particularly patent ductus arteriosus and pulmonary branch stenosis, cataracts, and congenital glaucoma would be unlikely in congenital infections other than congenital rubella.

Nonspecific laboratory testing is usually not helpful in the diagnosis of rubella postnatal infection of infants, children, and adults. Occasionally, mild leukopenia and atypical lymphocytes may be noted on the complete blood count (CBC). Otherwise, nonspecific screening laboratory test results are normal and unremarkable. Therefore, a laboratory diagnosis of rubella depends on specific viral diagnostic studies.

Rubella virus can be grown in a variety of primary and continuous cell lines. In many primary cell culture lines, rubella virus produces a persistent infection without obvious cytopathic effect.[79]Rubella does produce a cytopathic effect in some continuous cell lines (rabbit kidney cell line RK-13, Vevo cells, and SIRC cells) and in primary African green monkey cells.[79,81]

Virus isolation from a number of body sites (throat swab, urine, synovial fluid, amniotic fluid, cerebrospinal fluid) confirms the diagnosis of rubella infection. Virus excretion by individuals with postnatal rubella is transient and occurs from up to 10 days before the onset of symptoms (usually when the rash is noted) to 15 days after the onset of rash. Individuals with congenital rubella infection may excrete virus for many months and even years. Prolonged virus excretion (greater than 4 weeks) would be most consistent with congenital infection. A prenatal diagnosis of congenital rubella infection may be accomplished by isolation of rubella virus from amniotic fluid.[91]

Virus isolation of rubella is time-consuming and expensive. In addition, the paucity of rubella cases has markedly reduced the experience of viral diagnostic laboratories for identifying rubella in cell culture. Virus isolation of rubella is usually reserved for specific clinical situations (e.g., investigation of atypical arthritis, diagnosis of congenital rubella, prenatal investigation of congenital infection, and certain complications of postnatal rubella). If rubella infection is being considered, the viral diagnostic laboratory should be notified to enhance the likelihood that appropriate steps are taken to identify the rubella virus in cell culture. Consultation with a state laboratory or the Centers for Disease Control and Prevention (CDC) might be considered.

Serology has now become the most convenient and available method for establishing the diagnosis of both postnatal and congenital rubella infections. Currently, there are a number of serological assays (e.g., enzyme-linked immunosorbent assay, latex agglutination, immunofluorescent antibody, and radial hemolysis test) that can detect either rubella-specific immunoglobulin (Ig)G or rubella-specific IgM antibodies. Acute postnatal rubella infection can be presumed by the demonstration of a rubella-specific IgM antibody on a single acute serum. A fourfold increase or seroconversion in rubella antibody (either IgG or IgM) in paired acute and convalescent specimens (minimum of 7 days apart; optimally 14 to 21 days after acute sera) assayed by the same test would also establish a diagnosis of acute rubella infection. A single positive rubella-specific IgG antibody merely verifies infection with rubella, either from a past or recent infection. Rubella-specific IgM antibody results may be confounded by the fact that a

false positive occurs as a result of problems with the assay (poor specificity) or associated with other clinical conditions, such as recent infections with parvovirus or heterophile-positive EBV or persons with a positive rheumatoid factor.[92]Reinfection with rubella can also result in a positive rubella-specific IgM antibody.

Serologic diagnosis of congenital infection with rubella may be established by a positive rubella-specific IgM antibody in the affected newborn (not from cord blood) or persistence of rubella-specific IgG antibodies beyond 9 months in an infant with a compatible clinical syndrome who has not received the rubella vaccine and who is not from an endemic area. Intrauterine infection with rubella may be detected by the presence of rubella-specific IgM in fetal blood.[93,94]However, this antibody may not be detectable until 22 weeks of gestation.[93,94]

Placental biopsy, detection of rubella antigen with monoclonal antibody, cordocentesis with detection of rubella RNA by *in situ*hybridization, and PCR have also been used to establish a diagnosis of congenital rubella infection.[78,95,96]

Treatment—Rubella

Rubella is a mild and self-limited infection. Treatment is supportive and usually only indicated for the uncommon occurrence of fever and joint symptoms (arthralgia or arthritis). Immunoglobulin had been advocated for the prevention or modification of rubella in exposed, susceptible pregnant women.[78]

Immune serum globulin (ISG) was found to reduce symptoms but not consistently prevent viremia.[97]

Whether intravenous immunoglobulin (IVIG) could prevent viremia needs to be established. However, immunoglobulin might still be considered in the management of an exposed, susceptible pregnant woman for whom an abortion is not an option.[78]

Prevention/Infection Control Measures—Rubella

The currently licensed rubella vaccine is a live-attenuated rubella strain (RA 27/3) prepared in human diploid cell cultures.[82,85]This vaccine was licensed in the United States in 1979 and replaced previous live-attenuated vaccine strains (e.g., HPV-77 and Cendehill). The RA 27/3 induces an increased and more durable antibody response with fever side effects than prior rubella vaccines.

Ninety-five percent of individuals under 12 months of age receiving a single dose of the rubella vaccine develop serologic evidence of rubella immunity. Many of those who fail to have seroconversion after vaccination are seropositive by specialized, highly sensitive tests. Thus, rubella vaccination provides presumptive evidence of immunity. Rubella vaccine results in more than 90 percent protective efficacy after either natural exposure or artificial challenge studies. Rubella vaccine provides similar protection from reinfection and prevention of viremia as natural rubella. Available data suggest that one dose of rubella vaccine provides long-term and probably lifelong immunity. Currently, two doses of rubella vaccine are recommended in conjunction with the recommendation for two doses of the measles vaccine.

Vaccinated persons can shed vaccine virus for up to 28 days after vaccination, but there is no evidence that person-to-person vaccine virus transmission occurs. Vaccinated persons can develop subclinical

rubella infection as manifested by an increase in antibody titer, but they usually do not become viremic. Thus, if a previously immunized pregnant woman is exposed to natural rubella or a live rubella vaccine, the fetus is presumed to be protected. Congenital rubella syndrome has occurred only rarely in women with prior evidence of immunity (naturally acquired or vaccine-induced) before pregnancy.

Adverse reactions after administration of the rubella vaccine occur primarily in susceptible vaccinees. These adverse events are similar to, although less severe than, those of natural rubella. They appear less frequently with the current RA 27/3 vaccine strain. Fever, rash, and lymphadenopathy occur in 5 to 15 percent of susceptible individuals who receive the MMR vaccine approximately 5 to 12 days after vaccination. The actual role of each component of the vaccine on the development of fever is unknown. Transient joint pains (arthralgia or even transient arthritis) may occur 7 to 21 days after vaccination and are more common in adult women (approximately 25 percent of susceptible adult women). Chronic or persistent arthritis is reported in less than 1 percent of rubella vaccinees. The occurrence of moderate or severe arthropathy after administration of rubella vaccine is rare and not different from that which occurred in placebo recipients in a controlled trial.[85,98,99,100]

Transient central or peripheral nervous system manifestations have also been reported after receipt of rubella vaccine. A causal relationship between the rubella vaccine (RA 27/3) and recurrent/persistent joint symptoms, neuropathy, or collagen vacuolar disease has not been established and is unlikely.

Rubella vaccine should not be given to pregnant women. Pregnancy should be avoided for 4 weeks after rubella or MMR vaccination. From 1971 to 1989, the CDC monitored 321 known rubella-susceptible pregnant women who had inadvertently been vaccinated with rubella vaccine within 3 months before or up to 3 months after conception (94 received HPV-77 or Cendehill vaccine, 226 received RA 27/3 vaccine, and one was unknown). None of the 324 offspring had malformations compatible with congenital rubella. However, five infants (three exposed to HPV-77 or Cendehill and two exposed to RA 27/3) had persistent serologic evidence consistent with subclinical infection. Thus, the current vaccine poses a negligible risk of vaccine-associated malformations (estimated risk is 0 to 1.6 percent).[85]

Vaccination during or just before pregnancy is normally not an indication for elective abortion. Nevertheless, the vaccine should not be given to women who are known or suspected to be pregnant; vaccinated women should not become pregnant for 3 months after vaccination.

Minor illnesses, with or without fever, are not a contraindication for administering the rubella vaccine. However, individuals with moderate to severe acute illness should not be vaccinated until the illness has resolved.

Individuals with altered immunity (primary or secondary immunodeficiency) may be at increased risk for complications after receipt of live-virus vaccines. Rubella vaccine is contraindicated in individuals with B-lymphocyte (humoral), T-lymphocyte (cell-mediated), and combined (cell-mediated and humoral) immunodeficiencies. Children with complement deficiencies or phagocytic function deficiencies and human immunodeficiency virus–infected children who are not severely immunocompromised (Immunologic Categories 1 or 2) may receive the live rubella vaccine.[82]

Rubella vaccine response can be diminished if immunoglobulin has been administered recently. The interval between immunoglobulin administration and rubella vaccine administration that will ensure an adequate immune response to the rubella vaccine will vary by dose, route, and type of immunoglobulin preparation given. Rubella vaccine should not be given to an individual in a time period from 2 weeks before up to 3 months after the administration of a blood transfusion or immunoglobulin products (e.g., IVIG, IG, TIG). However, when the rubella vaccine is given with the measles vaccine or when high

doses of immunoglobulin are given (e.g., IVIG for Kawasaki disease), longer intervals between administration of the immunoglobulin product and vaccination with the live-virus vaccine (rubella or MMR) may be required to ensure optimal immune response (see Table 86-1).

The need to prescreen potential vaccinees for rubella antibodies is uncertain.[82,86] Prescreening is cost effective when the cost of serologic testing is low. When prescreening is not available or cost effective, rubella immunization of susceptible healthcare personnel (HCP) or other at-risk adults without a history of clinical rubella infection should be performed. Rubella immunization of a rubella-immune individual should have no adverse consequences.

Rubella represents a hazard to both pregnant HCP and pregnant patients. This provides two distinct goals for rubella control within healthcare settings: (1) protecting pregnant HCP and (2) protecting susceptible pregnant patients. The ethical basis for asserting that healthcare facilities should take special measures to protect their personnel is the potential heightened risk of rubella exposure and possible acquisition that results from a healthcare-related occupation. Individuals who have rubella may present to healthcare facilities for care. Children who have the congenital rubella syndrome would undoubtedly need medical services. These children excrete high titers of virus for prolonged periods of time (usually considered contagious until 1 year of age). Immunization programs aimed at protecting HCP should be (1) voluntary and (2) directed at postpubertal females.

Healthcare facilities have an absolute responsibility to ensure that all reasonable measures are taken to prevent exposure of susceptible pregnant patients to HCP or other patients with rubella. Consequently, HCP immunization programs can be justified because they serve to protect pregnant patients. These programs should (1) include all HCP, including males and infertile females; (2) be mandatory; and (3) be provided without cost to HCP. In practice, an appropriate rubella screening and immunization program for HCP should serve both purposes.

All HCP capable of becoming pregnant should be encouraged to verify their immunity to rubella by serologic testing and/or receiving the rubella vaccine.[85] Documentation of the presence of rubella antibody and receipt of the rubella vaccine are the only acceptable means to document rubella immunity. The clinical manifestations of rubella are not distinct enough to permit clinical diagnosis to serve as documentation of immunity.

Maternal rubella immunity may not provide absolute protection to the fetus.[87,88] Rubella transmission to the fetus of rubella-immune mothers has been reported on a few occasions. It seems prudent, therefore, that pregnant HCP, even if they are known to be rubella immune, not care for patients known to have rubella.

Healthcare settings with a relatively high risk of rubella exposure include the emergency department, nurseries, neonatal-care units, pediatric inpatient units, and outpatient clinics. Susceptible pregnant HCP should be aware of these high-risk areas.

The presence of rubella-susceptible HCP has led to sporadic outbreaks of rubella in hospitals.[82,84] Some rubella outbreaks have resulted in exposure of pregnant patients to rubella, although most of the transmission occurring in these outbreaks has been from patients to HCP and between HCP. The Advisory Committee on Immunization Practices and American Academy of Pediatrics recommend rubella vaccination for "persons (both male and female) working in hospitals and clinics who might contract rubella from infected patients or who, if infected, might transmit rubella to pregnant patients … unless there are contraindications."[82,83,84]

The American Hospital Association Advisory Committee on Infections Within Hospitals has recommended that "susceptible personnel, that is, men and women in all age-groups, who have contact with female patients in the childbearing years should be immunized" and that this immunization should be obligatory.[101]

PRECAUTIONS AND ISOLATION TECHNIQUES FOR PATIENTS WITH RUBELLA

For rubella, Droplet Precautions in addition to Standard Precautions are required for 7 days after the onset of the rash; a single room is preferred. Special air handling and ventilation are not necessary, and the door may remain open. No recommendation is made on wearing a mask for immune HCP. Gowns, facial protection, and gloves should be worn for patient contacts based on anticipated exposure per Standard Precautions.[31]

Contact Precautions are required for infants with or suspected of having congenital rubella until 1 year of age. Repeated negative cultures of the nasopharynx and urine of a congenitally infected infant after 3 months of age would suggest that the infant has a low likelihood for transmission. Accordingly, Standard Precautions should be followed.[31]

Postexposure rubella immunization has not been shown to prevent illness but is not associated with any harmful side effects. Theoretically, rubella vaccine given within 3 days of exposure might prevent illness.[81,82] Therefore, exposed nonpregnant susceptible women should receive rubella vaccination to prevent future infection if the identified exposure does not result in natural disease.

The routine use of serum immunoglobulin for postexposure prophylaxis of rubella in early pregnancy cannot be recommended because there are no efficacy data available.[101,102] However, if exposure occurs early in pregnancy (first 20 weeks) and termination of pregnancy is not an option, ISG administration can be considered within 72 hours of exposure. ISG (0.55 mL/kg) may prevent or modify infection in an exposed susceptible person. However, protection of the fetus has not been established, and there have been anecdotal reports of infants with congenital rubella after ISG administration to their mothers.[82]

Conclusions—Rubella

Rubella is a mild, self-limited disease that has its greatest health impact when maternal infection results in viremia and transmission to the fetus in early gestation. Maternal antibodies provide immunity and prevent viremia. Rubella antibodies are produced after natural infection and vaccination with a live-virus vaccine. In industrialized nations such as the United States, successful rubella vaccine programs have nearly eliminated indigenous cases of rubella and the congenital rubella syndrome. Until rubella immunization is universal in the developing world, there will still be significant numbers of children affected by the congenital rubella syndrome and a risk for importation of cases into nations with highly immunized populations.

Future Trends—Rubella

Ultimately, universal rubella immunization of young children and screening susceptible women of childbearing age would be optimal, but targeted approaches may be necessary until adequate resources

are available.

International Perspective—Rubella

Although postnatal rubella is typically a mild self-limited disease, congenital rubella syndrome can be a devastating disease affecting more than 100,000 children from developing countries. Successful immunization programs have markedly reduced rubella and the congenital rubella syndrome in the industrialized world, but most countries in Africa and Asia do not include rubella as part of their routine immunizations. In addition, many developing countries with rubella vaccine as part of the routine immunization schedule do not have adequate vaccine coverage (less than 80 percent) to result in decreases in the congenital rubella syndrome to levels occurring in industrialized nations.

In resource-poor countries, different approaches to rubella vaccine distribution have been undertaken. Immunization of adolescent girls or women of childbearing age does not significantly reduce the occurrence of rubella infections because most rubella infections occur in younger children unaffected by the vaccine administration. However, this approach can result in significant reductions in the congenital rubella syndrome.

APIC TEXT OF INFECTION CONTROL AND EPIDEMIOLOGY

Neisseria meningitidis

Author(s): Gio Baracco, MD, FACP
Associate Professor of Clinical Medicine

Division of Infectious Diseases
University of Miami Miller School of Medicine
Veterans Affairs Healthcare System
Miami, FL

Published: October 3, 2014

Abstract

Neisseria meningitidis*is an aerobic, Gram-negative diplococcus that colonizes the nasopharynx of many healthy individuals. Microbial and host factors combine to allow this organism to invade the bloodstream and get into the central nervous system, causing severe sepsis and meningitis. Hypervirulent strains may be transmitted from person to person through respiratory secretions, causing outbreaks of meningococcal disease. Several areas of the world, especially sub-Saharan Africa, have hyperendemic meningococcal disease. In the United States, most cases are sporadic; only approximately 2 percent of cases occur as outbreaks. However, outbreak-related cases have greater morbidity and mortality than sporadic cases. Patients with meningococcal disease should be promptly identified, and Droplet Precautions should be started when the diagnosis is initially suspected. Household contacts and individuals with direct exposure to patients' respiratory secretions require the administration of chemoprophylaxis. Five meningococcal serogroups cause the majority of cases: A, B, C, Y, and W-135; quadrivalent (A, C, Y, and W-135) polysaccharide and conjugate vaccines are available and recommended for populations at highest clinical or epidemiological risk of developing invasive meningococcal disease.*

Key Concepts

- Meningococcal disease is a severe, potentially lethal, transmissible infection. Appropriate infection prevention and other public health interventions are effective in preventing the spread of this disease within the hospital and the community.
- *Neisseria meningitidis*is transmitted via respiratory droplets from colonized or infected individuals to susceptible ones.

- Persons at high risk of infection (epidemiological or medical) should be vaccinated ahead of the exposure.
- Patients with confirmed or suspected meningococcal disease should be placed on Droplet Precautions to prevent nosocomial transmission of the disease.
- Post-exposure chemoprophylaxis is an effective way to prevent disease in exposed individuals.

Background

Neisseria meningitidis, also known as meningococcus, is the bacterium responsible for thousands of cases of severe sepsis and meningitis around the world. Meningococcal disease causes significant morbidity and mortality, especially surrounding epidemic outbreaks, and thus prevention of meningococcal transmission and disease is an important public health goal. Effective strategies for the prevention and management of meningococcal disease are available and based on a deep understanding of meningococcal pathogenesis and virulence, combined with widespread use of antibiotics and effective vaccines. These interventions have effectively diminished the impact of meningococcal disease and are discussed in detail in this chapter.

Basic Principles

EPIDEMIOLOGY

Vieusseux[1] published the first description of meningococcal disease in 1805, when he described an outbreak of severe sepsis and meningitis in Geneva, Switzerland. Meningococcal disease is still hyperendemic in many areas of the world. The highest burden of meningococcal disease occurs in the so-called meningitis belt in sub-Saharan Africa, an area comprising 22 countries from Senegal in the West to Ethiopia in the East, with an estimated total population of more than 400 million people.[2]

Epidemic and endemic diseases are caused primarily by six meningococcal serogroups: A, B, C, X, Y, and W-135. The incidence of meningococcal disease tends to be cyclical, with peaks and troughs occurring every 5 to 8 years. However, the incidence and pattern in each geographical area shows great variability. Serogroup A causes large outbreaks of meningococcal disease in the meningitis belt every 8 to 10 years since at least 1905, with attack rates as high as 1,000 per 100,000 people reported in affected communities.[3] Large outbreaks are rare outside of Africa, though in 2000 and 2001 several hundred pilgrims attending the Hajj in Saudi Arabia were infected with *N. meningitidis* serotype W-135.[4,5] Acquisition of this meningococcal serotype continues to be a problem for pilgrims to the Hajj,[6] despite aggressive measures taken by the Saudi government to prevent it.[7]

The Centers for Disease Control and Prevention (CDC) estimates that between 800 and 1,200 cases of invasive meningococcal disease occur annually in the United States. This corresponds to a case rate of 0.3 per 100,000 persons. This number has been declining steadily since the late 1990s.[8] A large population-based surveillance program has shown that in 2011, serogroups Y, B, and C accounted for 36 percent, 28 percent, and 25 percent of U.S. isolates, respectively.[9]

The age distribution of invasive meningococcal disease in the United States follows a multimodal distribution, with peaks in infants aged less than 5 years (especially between 0 and 6 months),

adolescents and young adults aged 16 to 21 years, and adults older than 65 years.[8]

Nasopharyngeal colonization is a prerequisite for the development of invasive meningococcal disease. Transmission occurs when nasopharyngeal secretions from a colonized person reach the upper respiratory tract of a susceptible individual via respiratory droplets or direct handling of respiratory secretions.[10]Because humans are the only host of *N. meningitidis*, all transmission is human to human.

No animal or environmental reservoirs have been identified, and the disease is not transmitted through arthropod vectors. Surveys performed in the absence of an outbreak demonstrate that approximately 10 percent of healthy persons will carry this organism at any one point in time. Crowded living conditions (e.g., military barracks or college dormitories),[11]active and passive smoking, and viral respiratory illnesses increase the likelihood of transmission by increasing the aerosolization of bacteria and by decreasing the local immunologic barriers to infection, leading to up to 50 percent carriage rates.[12]

However, only a small minority of those colonized will develop invasive meningococcal disease. The rate of carriage per se is not necessarily a predictor of meningococcal outbreaks but seems to be a marker indicating that conditions for enhanced transmission are present. Development of invasive disease seems to be more a factor of being colonized with the right strain. Genetic recombination and mutations of the bacterium in the population contribute to the development of more virulent strains, increasing the risk of serious disease. For instance, the risk of meningococcal disease in household contacts of infected patients is approximately 3 per 1,000 persons,[13]which is approximately 500 to 800 times greater than the risk of the general population.[14]In addition, some host factors will also make it more likely that a colonized person develops invasive disease, though patients with these conditions account for only a minority of cases with invasive meningococcal disease. These host factors include functional or anatomic asplenia, a deficiency of properdin, and a deficiency of terminal complement components.

In the United States, meningococcal disease occurs most often during the winter and early spring.[14]Most cases are sporadic, and much less often (approximately 2 percent) they occur as outbreaks or case clusters. A total of 69 outbreaks of meningococcal disease, representing 229 cases, were reported between 1994 and 2002. Forty-three (62 percent) of these outbreaks involved *N. meningitidis*serogroup C, 17 (25 percent) involved serogroup B, and 9 (13 percent) involved serogroup Y. No outbreaks of *N. meningitidis*infection involving serogroups A or W-135 were detected.[15]Recently, several clusters of group C invasive meningococcal disease have been reported in men who have sex with men in the United States, Canada, and several European countries.[16,17]However infrequent, outbreaks remain an important public health issue. Patients with outbreak-associated illness are more likely to die than patients with sporadic disease. The High case fatality rate associated with outbreaks of meningococcal disease may be related to the strains involved, the host, or the environment.[15]

Healthcare-associated transmission of *N. meningitidis*and secondary cases of meningococcal disease can occur. The index case for healthcare-associated spread may have pneumonia or tracheobronchitis. Aerosolization of respiratory secretions is a risk factor for disease. In one study of a patient with *N. meningitidis*pneumonia, 8 of 92 hospital personnel who had cared for the patient became carriers. In another case of serogroup B meningococcal meningitis, a nurse who assisted with intubation of the case patient developed serogroup B meningococcal meningitis.[18]

Transmission to laboratory workers is also a concern and reinforces the importance of masks, gowns, and gloves when manipulating secretions or potential aerosols, biosafety cabinet (BS-2) precautions for

working with cultures of *N. meningitidis,*and immunization of microbiology laboratory personnel. In 2002, the CDC reported two cases of fatal laboratory-associated meningococcal disease that occurred in microbiologists who had handled clinical specimens of *N. meningitidis*serogroup C. This study identified an additional 14 cases of laboratory-acquired meningococcal disease occurring in the preceding 15 years through a Listserv survey. The overall fatality rate in this series was 50 percent.[19]

CLINICAL PRESENTATION

The clinical manifestations and the degree of severity of meningococcal disease vary widely. Patients with meningococcal infection present with or without involvement of the central nervous system in about equal proportions. One of the classic features of meningococcal disease is the presence of a petechial or purpuric rash that appears concomitantly with fever, malaise, and headache.

The most common forms of invasive meningococcal disease can be summarized as follows:[20]

1. Bacteremia without sepsis. Meningococcal disease may present as a nonspecific febrile illness. Patients are often diagnosed as having a viral upper respiratory infection or viral exanthem and are frequently discharged from the hospital without specific antibiotic therapy. The diagnosis is made when blood cultures return with *N. meningitidis*. Many patients recover spontaneously.
2. Meningococcemia without meningitis (27 percent of cases). Patients with this syndrome present with fever, malaise, and a petechial or purpuric rash that may progress to purpura fulminans, a condition characterized by cutaneous hemorrhage and necrosis. This syndrome is accompanied by the rapid development of hypotension, acute adrenal insufficiency (Waterhouse-Friedrickson syndrome), multiorgan failure, and severe coagulopathy from disseminated intravascular coagulation, and may result in the patient's death within a few hours from the onset of symptoms.
3. Meningitis with or without meningococcemia (70 percent of cases). The classic triad of clinical manifestations suggesting meningitis—headache, fever, and meningeal signs—occurs in only about one quarter of the patients with meningococcal meningitis. The patient's mental status varies from normal to comatose. Deep tendon reflexes are usually normal, and no pathologic reflexes are present. The cerebrospinal fluid of patients with untreated meningococcal meningitis is usually cloudy and has pleocytosis with a predominance of neutrophils, low glucose, and high protein levels. In most of the cases, the organisms are seen on Gram stain or can be identified using latex agglutination assays. The culture is almost invariably positive as long as the sample was obtained before the administration of antibiotics.
4. Meningococcal meningoencephalitis. Patients present with a profoundly altered mental status, meningeal signs, and an abnormal cerebrospinal fluid. The deep tendon and superficial reflexes are altered (either absent or rarely hyperactive). Pathologic reflexes are frequently present.
5. Meningococcal pneumonia. Patients present with fever, cough, and chest pain. A history of a recent upper respiratory infection is present in about half of the patients, and viral infections such as influenza may predispose frail colonized patients to develop meningococcal pneumonia. Establishing the specific etiologic diagnosis in these patients is challenging, because nasopharyngeal carriage of *N. meningitidis*is common and blood cultures have low yield. However, the prognosis seems to be good, with no fatalities reported in a cohort of 68 Air Force recruits with group Y meningococcal pneumonia treated with penicillin.[21]

Variations of these manifestations can occur, and patients can progress from one form to the other during the course of their disease. Less common syndromes, including urethritis, supraglottitis, and a chronic bacteremic syndrome with rash and arthritis similar to chronic gonococcal disease have also

been described. Small children and elderly patients also tend to present with atypical and protean clinical manifestations.

DIAGNOSIS

The diagnosis of meningococcal disease is made by identification of *N. meningitidis*from blood, cerebrospinal fluid, or other sterile fluids from patients with compatible signs and symptoms. Colonization can be ascertained by isolating the microorganism from nasopharyngeal secretions.

*Neisseria*species are Gram-negative cocci usually seen in pairs with the adjacent sides flattened. *N. meningitidis*grows best in a moist environment at 35°C to 37°C with 5 to 10 percent carbon dioxide. It grows well on blood agar base, supplemented chocolate agar, trypticase soy agar, Mueller-Hinton agar (for sterile body sites), and selective media such as Thayer-Martin agar (to detect nasopharyngeal colonization). Samples need to be transported and plates should be set up promptly, because the microorganism does not tolerate desiccation well. Growth of oxidase-positive colonies and Gram-negative diplococci with the right clinical context provides a presumptive identification of *N. meningitidis*. Fermentation of glucose and maltose, but not sucrose, lactose, or fructose, may be used for species confirmation. Molecular methods, such as polymerase chain reaction (PCR) techniques, may supplement culture for the detection of meningococcus, especially in patients previously treated with antibiotics.[20]

N. meningitidis, unlike the other human pathogenic *Neisseria*(*N. gonorrhea*), has a polysaccharide capsule that serves as an antiphagocytic virulence factor. The capsule is antigenically and chemically unique and allows for the classification of meningococcal strains into at least 13 serogroups. However, almost the entire disease burden occurring worldwide is caused by only six serogroups: A, B, C, W-135, X, and Y. The serologic group may be determined by a slide agglutination test, using first polyvalent and then monovalent antisera.[3]Meningococci may be further classified on the basis of their outer membrane proteins (protein serotype), and lipo-oligosaccharides (immunotype).[20]

Meningococcal populations are diverse and dynamic, and epidemiological investigations require high-resolution techniques. Molecular subtyping with the use of multilocus enzyme electrophoresis, pulsed-field gel electrophoresis, or DNA sequence analysis can be helpful in identifying closely related strains with the potential to cause outbreaks and in understanding the genetic characteristics of *N. meningitidis*.[22]

MANAGEMENT

Prompt administration of effective antibiotics dramatically improves the outcome of patients with invasive meningococcal disease. With adequate treatment, patients with meningococcal meningitis have a mortality rate of less than 5 percent.

Sulfonamides were the first antibiotic class used effectively to treat invasive meningococcal disease. However, the emergence of resistance in a significant proportion of pathogenic strains has resulted in the discontinuation of the use of this class of antibiotics.[23]

Penicillin G and third-generation cephalosporins such as ceftriaxone are consistently active against *N. meningitidis*, have potent bactericidal activity, and have acceptable penetration into the central nervous system.[20]Although rare, penicillin-insensitive strains of *N. meningitidis*have been reported in Europe and the United States. These organisms usually retain susceptibility to ceftriaxone and cefotaxime. It is for

these reasons that ceftriaxone at doses of 1 to 2 g every 12 hours is considered the antibiotic of choice for the treatment of invasive meningococcal disease. Penicillin G 300,000 U/kg/d up to a maximum of 24 million units per day administered every 2 hours or by continuous infusion is a perfectly reasonable alternative. Chloramphenicol, at doses of 25 mg/kg intravenously every 6 hours up to a maximum dose of 1 g every 6 hours, can be used in patients intolerant to beta-lactam antibiotics.

PREVENTION

Prevention of meningococcal disease must occur at several levels. Public health interventions to decrease the incidence of meningococcal disease in the community include immunization of high-risk individuals, advice to travelers, and chemoprophylaxis of household contacts of patients with meningococcal disease. At the hospital level, rapid identification and institution of Droplet Precautions based on suspicion of meningococcal disease, appropriate antibiotic therapy of the patient, and chemoprophylaxis of healthcare personnel who were in direct contact with the patient's nasopharyngeal secretions are the most important interventions to take. In addition to observing appropriate biosafety practices, laboratory technicians working in the microbiology laboratory should be immunized against *N. meningitidis*.

Immunization

There are currently four licensed meningococcal vaccines in the United States. A quadrivalent (A, C, Y, W-135) polysaccharide meningococcal vaccine (MPSV4) was licensed in the United States in 1978. The polysaccharide vaccine's main limitation is that its immunogenicity and duration of protection is limited. In addition, it has little effect on nasopharyngeal carriage rates and therefore does not provide herd immunity. In January 2005, the U.S. Food and Drug Administration licensed a new meningococcal conjugate vaccine (MenACWY-D), in which the antigens are conjugated to diphtheria toxoid. This conjugate vaccine provides an enhanced primary response among infants and a strong anamnestic response at re-exposure. It is currently licensed as a one-dose vaccine for individuals aged 2 to 55 years and as a two-dose vaccine for children 9 to 23 months old. In 2010, a second tetravalent conjugate vaccine was licensed (MenACWY-CRM). In this vaccine, the meningococcal antigens are bound to CRM_{197}, a nontoxic form of diphtheria toxin. It is approved as a single-dose vaccine for people ages 2 to 55 years. A third meningococcal conjugate vaccine was approved in 2012 (Hib-MenCY-TT). This is a combined vaccine with antigens to *Haemophilus influenzae* type B and serotypes C and Y of *N. meningitidis* bound to tetanus toxoid. It is approved in a four-dose regimen for infants aged 6 to 18 months. All four vaccines are safe and effective. Efficacy was established for MPSV4 by direct clinical trials of monovalent serogroups A and C and combined A/C vaccines and by inferring immunity based on equivalent serum bactericidal antibody (SBA) levels for serotypes Y and W-135. Efficacy of all three conjugate vaccines has been inferred by using SBA levels against each of the antigens in the vaccines. All currently available vaccines have the limitation of not protecting against infection caused by *N. meningitidis* serogroup B.[8]

The CDC's Advisory Committee on Immunization Practices (ACIP)[8] recommends that the following groups of individuals receive meningococcal immunization:

- All children at age 11 or 12 years or at age 13 to 18 years, if not previously vaccinated, should receive a single dose of a MenACWY vaccine. A booster dose should be administered at age 16 to 18 if the first dose was received prior to the 16th birthday.
- Persons at increased risk for meningococcal disease:
  - Persons with persistent terminal complement component deficiency, anatomic or functional asplenia

- Travelers or residents of countries where meningococcal disease is hyperendemic or epidemic
- First-year college students age 21 or under living in residential housing.
- Microbiologists who are routinely exposed to isolates of *N. meningitidis*.
- Persons at risk during a community outbreak attributable to a vaccine serogroup

Hib-MenCY-TT is indicated for children 2 to 18 months old. A MenACWY vaccine is preferred for children aged 9 months and older, as well as for adults with any of the preceding indications who are aged 55 years or under. MPSV4 is the only vaccine indicated for adults older than 55 years of age, though persons older than 55 years who were vaccinated previously with MenACWY and are recommended for revaccination should continue to receive a MenACWY vaccine.

Human immunodeficiency virus (HIV) infection is not an indication for routine MenACWY vaccination. However, if an HIV-positive patient has another indication for vaccination, he or she should receive a two-dose primary series, administered 8 to 12 weeks apart, because patients with HIV do not respond optimally to a single dose.[8]

The CDC has recommended thresholds for initiating vaccination campaigns in the setting of an outbreak.[8]A vaccination campaign should be started when at least three cases of meningococcal disease caused by the same serogroup have been identified in a community or organization in less than 3 months, with a resulting primary attack rate greater than 10 cases/100,000 population. In organizational settings, the occurrence of even two cases in such a short period may warrant consideration of a vaccination campaign. These recommendations contrast with those of the World Health Organization, which recommends a threshold of five cases in 1 week for populations of less than 30,000 people, or 15 cases per 100,000 population per week in populations of 30,000 to 100,000 people.[24]

Chemoprophylaxis

An important intervention for the prevention of sporadic meningococcal disease is antimicrobial chemoprophylaxis of close contacts of a patient with invasive meningococcal disease.[8]Close contacts are individuals who are exposed within 7 days of the onset of symptoms and who belong to one of the following groups:

- Household members
- Child-care center contacts
- Anyone directly exposed to the patient's oral secretions (e.g., through kissing, mouth-to-mouth resuscitation, endotracheal intubation, or endotracheal tube management)
- For travelers, antimicrobial chemoprophylaxis should be considered for any passenger who had direct contact with respiratory secretions from an index patient or for anyone seated directly next to an index patient on a prolonged flight (i.e., more than 8 hours).

Antimicrobial chemoprophylaxis is not indicated for contacts of patients with *N. meningitidis*isolated only from nonsterile sites (oropharyngeal, conjunctival, or respiratory specimens). Antibiotics are also not indicated for asymptomatic nasopharyngeal carriers of *N. meningitidis*.

Chemoprophylaxis should be initiated as soon as possible, ideally within 24 hours of initial exposure. Conversely, chemoprophylaxis administered more than 14 days after onset of illness in the index patient is probably of limited or no value. Oropharyngeal or nasopharyngeal cultures are not helpful in

determining the need for chemoprophylaxis and might unnecessarily delay institution of this preventive measure.[8]

Rifampin, ciprofloxacin, and ceftriaxone have comparable efficacy and are good alternatives. The patient's age and presence of contraindications, and clinician and patient preference, determine the selection of antibiotic.

Recommended regimens[8] are as follows:

- For children under 1 month of age: rifampin 5 mg/kg every 12 hours for 2 days
- For children over 1 month of age: rifampin 10 mg/kg (maximum 600 mg) every 12 hours for 2 days, or (for children aged <15 years) ceftriaxone 125 mg as a single intramuscular dose
- For adults: ciprofloxacin 500 mg by mouth as a single dose, rifampin 600 mg by mouth every 12 hours for 2 days, or ceftriaxone 250 mg as a single intramuscular dose

Azithromycin is not recommended as first-line chemoprophylaxis, but one study showed that a single 500-mg dose was effective in eradicating nasopharyngeal carriage and may be considered for prophylaxis if there is sustained ciprofloxacin resistance in a local community.[8]

Ciprofloxacin should not be used for children unless there are no other viable alternatives. Both rifampin and ciprofloxacin should not be used in pregnant or lactating women because of their teratogenic potential. Rifampin may impair the efficacy of oral contraceptives, so alternative contraceptive methods should be advised while a patient is taking this drug.

Systemic antibiotics other than third-generation cephalosporins used to treat meningococcal disease are ineffective in eradicating meningococcal nasopharyngeal carriage, so patients with meningococcal disease treated with any regimen other than ceftriaxone or other third-generation cephalosporins should also be given chemoprophylaxis.[8]

Future Trends

Improving the use of existing vaccines across populations, performing research and development of more broadly effective vaccines, ensuring vaccine availability, and having the ability to perform rapid diagnosis are major areas for future work.

International Perspective

Although relatively few cases are diagnosed in the United States, meningococcal disease is highly endemic in many areas of the world. *N. meningitidis* is responsible for large epidemics (causing thousands of deaths) in many West and Central African countries (the so-called meningitis belt). Prevention efforts in developing countries include routine vaccination of the entire population (i.e., Saudi Arabia) or school children (i.e., Sudan). The World Health Organization promotes a three-pronged approach to the public health response of epidemic meningococcal disease in developing countries, involving epidemic preparedness (surveillance, case detection and investigation, and laboratory confirmation), prevention (vaccinating all individuals 1 to 29 years of age in the African meningitis belt

with meningococcal A conjugate vaccine), and epidemic response through appropriate case management and reactive mass vaccination campaigns.[25]

Travelers to the meningitis belt in sub-Saharan Africa during the dry season (December to June) or to areas affected by meningococcal outbreaks are advised to be vaccinated. It is recommended that travelers be vaccinated at least 10 days before travel to allow immunity to build. However, vaccination still should be provided for travelers leaving in fewer than 10 days.[26]The government of Saudi Arabia requires that visitors traveling to Mecca during the annual Hajj and Umrah pilgrimages obtain a tetravalent vaccine at least 10 days before their arrival in the country, and that the vaccination has occurred in the previous 3 years. Updated information regarding ongoing epidemics and vaccination requirements for travelers can be found on the CDC's Web site (**http://www.cdc.gov**).

APIC TEXT OF INFECTION CONTROL AND EPIDEMIOLOGY

Parvovirus

Author(s): Jeanette Lepinski, MSN, RN, CIC
Director of Infection Prevention & Control

Sinai Health System
Chicago, IL

Published: October 3, 2014

Abstract

Human parvovirus B19 is an enterovirus and the causative agent of erythema infectiosum. This illness, with its characteristic rash, commonly occurs during childhood and produces long-lasting immunity. Often, outbreaks are cyclical, lasting 1 or more years, with 3 or more years of low-level activity. Transmission likely occurs by the droplet mode. Additionally, vertical and parenteral transmission have been reported. The illness is generally mild and self-limited. The typical "slapped cheek" rash develops when the virus can no longer be isolated from respiratory secretions. The risk for transmission is minimized with appropriate infection prevention practices, such as hand hygiene, respiratory etiquette, and Droplet Precautions.

Key Concepts

- Human parvovirus B19 causes erythema infectiosum, also called fifth disease, slapped cheek rash, or gloves and socks syndrome.
- Human parvovirus B19 enters through and infects the respiratory tract, then seeds the bone marrow.
- Human parvovirus B19 can be transmitted parenterally through blood and blood product transfusion.
- Outbreaks are often cyclical.
- Approximately half of adults have evidence of antibodies to human parvovirus B19.
- Infection during pregnancy may cause variable effects in the fetus depending on gestational age.
- Human parvovirus B19 has been implicated in other disease processes.
- Human parvovirus B19 has been identified as the primary causative agent of transient aplastic crisis.
- Treatment for infection with the virus includes supportive care.
- Severely immunocompromised individuals may benefit from intravenous immunoglobulin therapy.

- Infection prevention in healthcare settings includes Droplet Precautions in addition to Standard Precautions.

Background

Human parvovirus B19 (PVB19) was first identified in 1974 and was subsequently recognized as the causative agent of a globally endemic mild or asymptomatic human infection. The illness is common in children and manifests with cold-like symptoms followed by a "slapped cheek" rash with lace-like pupura on the trunk, arms, and legs. It may also manifest in a glove and socks pattern. Illness in adults is not uncommon and may manifest with flulike symptoms, with severe persistent arthralgias. Approximately half of the population is immune due to previous infection. Outbreaks often occur in school settings and may be cyclic over several years. The virus is spread via the respiratory tract through droplets and secretions, but infection can occur from blood and blood products or from mother to fetus via vertical transmission.

Basic Principles

PVB19 is in the *Parvoviridae*family of DNA viruses. Although most of the viruses in this family infect a variety of animals, PVB19 has been limited to humans. Because there are other disease processes associated with this virus, or the illness may be similar to others, a definitive confirmation or differential diagnosis may be required. The infection may be prolonged or more severe in immunocompromised individuals. Confirmation of infection may be verified in the laboratory through a variety of tests. Infection prevention includes Transmission-based Droplet Precautions in addition to Standard Precautions.[1]

PARVOVIRUS INFORMATION

Identification of Infectious Agent

Taxonomy

The *Parvoviridae*family consists of a large group of small, single-stranded DNA viruses approximately 20 to 25 nm in size. The family includes 41 known viruses recognized as individual species and is divided into two subfamilies: *Densovirinae*and *Parvovirinae*. The *Densovirinae* subfamily includes viruses infecting insects, whereas the *Parvovirinae*infect animal species. The subfamily of *Parvovirinae*may be further separated into three genera: *Parvovirus*, *Dependovirus*, and *Erythrovirus*.[2,3]

*Parvovirus*is found in many animal species, and some are of veterinary interest. *Erythrovirus*comprises PVB19, V9, and parvoviruses. *Dependovirus*includes adeno-associated virus (AAV) serotypes 1 to 6. This group of viruses is generally species specific.[2,3,4,5,6]For example, PVB19 has been shown to cause disease only in humans.[7]

Human Parvovirus B19

In 1975, PVB19 was first isolated from serum specimens of healthy blood donors and named as such for the position occupied on the laboratory testing plate. The virus was originally thought to have a single genotype. However, three discrete serotypes have been identified. Virus serotypes 2 and 3 have

been found to have higher prevalence in the North and South America and Western Europe. Strain type 3 has been found to be endemic in certain parts of Africa. The prevalence and clinical significance of these serotypes is not presently known.

This virus is nonenveloped and resistant to detergents/solvents and remains stable in the environment for prolonged periods. PVB19 is also thermostable and can survive at 60°C (140°F) for up to 12 hours.[5,7,8,9,10]In one study, PVB19 was inactivated after being suspended in 5 percent or 25 percent human serum albumin solution, phosphate-buffered saline, or complete medium at 60°C. However, the virus was resistant to heat inactivation in liquid 60 percent sucrose.[10]Another study found intravenous immunoglobulin (IVIG) treated with heat and polyethelene glycol was rapidly inactivated to below detectable levels. Other studies have shown that PVB19 could be sensitive to a 5-minute contact time with accelerated hydrogen peroxide (5,000 ppm) or sodium hypochlorite (3,000 to 5,000 ppm) at room temperature.[11,12]Formaldehyde and β-propriolactone have been shown to destroy the virus' antigenicity.[13]Due to the size of the virus, filters with a pore size of 35 nm do not effectively filter out the virus.[14]

Epidemiology and Transmission

Occurrence

The virus is generally asymptomatic but may be manifested as a papular purpuric rash resembling slapped cheeks. This condition is also known as gloves and socks syndrome, erythema infectiosum, or fifth disease.[15](The designation fifth disease was given because it was listed as the fifth of six common rash-producing diseases of childhood, which included measles, scarlet fever, rubella, Dukes disease, and roseola.)

PVB19 is more commonly acquired during childhood in late winter or early spring. Approximately half of all adults have long-lasting immunity as a result of previous infection.[16]Approximately 90 percent of elderly persons are thought to be seropositive for PVB19, as are 40 to 60 percent of young adults, 30 to 40 percent of adolescents, and 2 to 15 percent of children aged 1 to 5 years.[14]

Outbreaks

Outbreaks of PVB19 are often cyclical, lasting 1 to 2 years, followed by 3 or more years of low-level activity. Epidemics among school-aged children in the United States usually begin in midwinter and end at summer recess. During school outbreaks, approximately 20 to 30 percent of susceptible teachers may become infected. Additionally, approximately 50 percent of susceptible household members become infected when exposed.[15,16]

Infectious Process

PVB19 enters through and infects the respiratory tract, then seeds the bone marrow, where immature red blood cells (RBCs) and lymphocytes (B and T cells) are infected. The virus is lytic, shutting off RBC production and causing a reticulocytopenic anemia.

The incubation period is usually 4 to 14 days after exposure. However, the infection may present up to 20 days later. The viremic phase occurs approximately 6 days after infection and usually persists for up

to a week.[15,16,17,18]Viral DNA may be detected in the blood, respiratory secretions, urine, tears, synovial cells, liver, and endothelium of the myocardium during the viremic stage.[19]Mild symptoms may be present before the antibody response is detected and at the peak of viremia. Ten to 13 days after infection, an immunoglobulin M (IgM) antibody response is mounted, viremia begins to clear, and reticulocytosis develops in an attempt to correct the anemia. Because the rash of erythema infectiosum develops after the antibody response has begun, it is presumably caused in part by the immune response.

Thus, the illness can be biphasic, with some systemic symptoms associated with joint pain, viremia, and rash and others associated with an immune response to the infection. Additionally, immune complexes identified in PVB19 infection may contribute to the disease process. In individuals with normal RBC production, a significant anemia usually does not develop. However, persons with sickle cell disease, systemic lupus erythematosis, or hereditary spherocytosis who require increased RBC production may rapidly develop severe anemia.[17,19,20]

Primary Mode of Transmission

The mode of PVB19 transmission occurs by the respiratory route through respiratory secretions and droplets of saliva.[1,15]During the viremic period, coldlike symptoms may be present. Person-to-person spread is through direct contact with the respiratory secretions of infected individuals, especially with close contact for prolonged periods of time. The slow rate of spread in schools suggests transmission involves environmental fomites. Sharing eating or drinking utensils facilitates viral spread. By the time the characteristic slapped cheek rash has developed, the virus is no longer found in respiratory secretions and the host is no longer considered contagious. If PVB19 advances to transient aplastic crisis (TAC), viremia generally persists and the virus can still be transmitted to others.[15,18]

Parenteral Transmission

PVB19 can be transmitted parenterally through blood and blood product transfusion. It can be transmitted to persons with hemophilia who receive coagulation factor concentrates treated by standard blood-bank methods.[21]This virus can also be transmitted to individuals receiving plasma-derived coagulation factor concentrate treated by the solvent/detergent method for inactivating viruses. More recently, Kooistra and colleagues[22]demonstrated that during epidemic seasons, blood donations with high levels of parvovirus viremia that are devoid of concurrent antibodies may play a role in infecting immunocompromised and parvovirus-naïve recipients.[22]

Vertical Transmission

Of childbearing women, 50 to 60 percent are already immune to PVB19. However, when pregnant women become infected, vertical transmission occurs in approximately one-third of fetuses.[21,23,24]The infection is thought to occur in approximately 1 in 400 pregnancies. Spontaneous abortion occurs in less than 10 percent of pregnant females who contract the virus within the first trimester.[23,24,25]The highest risk for fetal death seems to occur when PVB19 is contracted within the first 20 weeks of gestation.[13,26,27]

Transmission in the Healthcare Setting

PVB19 transmission has been documented to healthcare personnel in the healthcare setting. Transmission may occur with unprotected respiratory exposure to persons with the virus via the droplet route. Percutaneous exposure to contaminated blood or blood products has been documented. In addition, transmission from individuals with aplastic crisis to other susceptible individuals has been reported.[28,29]

Infectivity and Incubation Periods

Incubation Period

The incubation period for PVB19 varies depending on the clinical manifestation of the disease. A range of 4 to 14 days is most common, but it may be as long as 21 days. With natural infections, such as those that occur in households, the incubation period extends from 13 to 18 days. Two to 3 weeks after infection, rash and joint symptoms may develop.[22]

Infectivity

Viremia peaks during the first 2 days of the illness, during which time the symptoms are similar to the common cold. Generally the illness is contagious for 4 to 5 days before the rash appears. Children with fifth disease caused by PVB19 are generally considered noncontagious by the time the slapped cheek rash appears. This is different from other illnesses that manifest rashes, such as measles, in which the person is contagious during the rash stage.

In individuals who develop PVB19 infection with TAC, viremia generally persists and the infectious period lasts for the duration of the illness, usually approximately 7 days after the onset of symptoms. Peak viremia generally occurs 7 to 12 days after exposure and may last for 3 to 7 days. However, those who develop chronic infections may remain infectious for years until viremia resolves.[1,22,30]

Clinical Manifestations

Erythema Infectiosum

PVB19, the causative agent of erythema infectiosum, generally produces a mild, self-limited illness most often seen in school-aged children. Because the illness is typically mild, it generally resolves without medical treatment in otherwise healthy individuals. This form of PVB19 typically begins with low-grade fever, malaise, or coldlike symptoms. Several days later, an erythematous facial rash and a reticulated red rash on the trunk and extremities appear. This rash may occasionally cause itching and usually resolves within 7 to 10 days. However, it may come and go over a period of weeks and occasionally months. This virus has been associated with various other rashes, including vesicular, petechial, purpuric, morbilliform, and papular rashes.[30,31]Of note, meningoencephalitis also may be associated with PVB19 infection. The symptoms may mimic those of bacterial meningitis. PVB19 DNA has been found in the CSF of this population but not in the brain tissue.[31,32,33,34]

Polyarthralgia and Polyarthritis

PVB19 has been associated with various forms of autoimmune diseases that affect the large and small blood vessels, joints, and connective tissue. Although the molecular basis of the autoimmune phenomena is unclear, it is possibly related to apoptotic damage and an increased production of

cytokine.[3]Additionally, the pathogenesis involving arthralgias may be related to immune complexes deposited in synovial fluids.[13,35,36]

PVB19 is generally manifested as polyarthropathy in adults. Arthralgias and arthritis have been reported in all joints, but most frequently occur in the distal joints. Most frequently, the hands, wrists, and knees are affected with pain and swelling, generally resolving within 1 to 2 weeks. Bilateral joint pain is a common complaint and occurs more often in adults with PVB19 infection. Arthritic conditions usually resolve over several weeks without prolonged disability. However, symptoms can persist for months and even years.[37,38]

An association between PVB19 and rheumatoid arthritis appears to exist. One study found that 62 percent of controls without arthralgic conditions had positive immunoglobulin G (IgG) titers, indicating past infection, whereas only 9 percent were positive for viral DNA and had no evidence of rheumatological disease.[39]Rheumatoid factor may routinely be found in PVB19-infected persons who have a history of rheumatoid conditions. In addition to arthralgias, inflammatory arthritis occurs in almost 50 percent of adult patients, with 15 percent of cases resulting as an aftermath of infections with PVB19.[40]There is evidence to suggest an association of PVB19 infection and juvenile rheumatic diseases. In one study, 35 percent of children with rheumatic disease were found to have detectable amounts of PVB19 DNA in their serum or synovial fluid. PVB19 infection should be considered in the differential diagnosis of children and adults initially presenting with polyarthralgias/polyarthritis.[39]A relationship has been suggested between chronic PVB19 infection, and the following: fibromyalgia syndrome, chronic fatigue syndrome, and systemic lupus erythromatosis.[34,40]However, one investigation reported that none of the fibromyalgia syndrome cases had evidence of PVB19 viremia as detected by polymerase chain reaction (PCR) analysis.[40]

Infections in the Immunocompromised Host

PVB19 infection in immunocompromised individuals, including individuals infected with human immunodeficiency virus (HIV), and those with congenital immunodeficiencies receiving immunosuppressive therapy for cancer, leukemia, lymphoma, renal transplant, or other solid organ transplants, can result in pure RBC aplasia, chronic infection, and chronic severe anemia. Chronic bone marrow suppression has been described in this population.[30,40,41,42,43,44,45,46,47]This severe anemia is caused by the lysis of erythroid precursor cells. Making the diagnosis is particularly important, because these patients often respond to treatment with IVIG. Therefore, this infection should be considered in the differential diagnosis in the presence of reticulocytopenic anemia in immunosuppressed patients.[2,5] IVIG therapy induces reticulocytosis and generally resolves the anemia.[2,42,43]

Patients with Renal Disease and Renal Transplant Recipients

PVB19 has been epidemiologically linked as the causative agent of acute glomerulopathy and is associated with the anemia present in individuals with end-stage renal disease or postrenal transplantation. Some case reports have also implicated the virus as the potential cause of glomerulonephritis and collapsing glomerulopathy; however, a causal relationship was not been established.[44]The typical onset of anemia after PVB19 infection in renal transplant recipients occurs within 2 to 34 months. In one study the virus was detected in 23 percent (11 patients) of renal transplant recipients who presented with anemia. Another study by Porignaux and colleagues found that

10 percent of the patients being followed developed PVB19 viremia in the first year posttransplant.[46]

Another study found the median time to onset of PVB19 disease after transplant was 7 weeks. Anemia was present in 98.8 percent of patients, followed by leukopenia in 37.5 percent and thrombocytopenia in 21 percent of patients. The following were also reported in association with PVB19 infection: hepatitis, myocarditis, and pneumonitis. Finally, 10 percent of patients experienced allograft tissue loss or dysfunction related to PVB19 disease. PVB19 infection should, therefore, be considered in the differential diagnosis in the presence of anemia in post-renal transplant patients. Not all patients who have undergone transplant are able to mount an antibody response to PVB19 infection; thus, PCR testing may be necessary to make an accurate diagnosis in immunocompromised individuals.[45]

Fetal and Neonatal Infection

Approximately 50 percent of women of childbearing age are susceptible to PVB19 infection. The highest risk for contracting the virus during pregnancy occurs during outbreaks in the community. During such epidemics, nonimmune pregnant women who have more frequent contact with children are at the greatest risk for contracting the illness. The risk for infection varies by the type of exposure. Approximately one-third of fetuses with B19 infection may be adversely affected. Outcomes are related to gestational age at which infection occurs, with the worst outcomes between 4 and 20 weeks' gestation. Prior to 4 weeks, there is no intrauterine transmission and after 20 weeks there is no risk of hydrops.[23,24,25]

The fetus has an immature immune system and does not have the ability to mount an adequate response to the infection. Severe anemia with hemoglobin counts as low as 2 g/dL have been reported. When anemia is severe, congestive heart failure and nonimmune fetal hydrops may develop. Nonimmune hydrops secondary to PVB19 infection occurs in less than 3 percent of pregnancies at approximately 2 to 4 weeks after maternal infection. Because myocardial cells in the fetus can also be infected, there may be direct damage to the heart itself.[4,5,6,7,12,15,25,30,48]

When PVB19 is contracted within the first trimester, there is an increased risk for anencephaly, polymicrogyria, and spontaneous abortion. Infections occurring in the second and third trimesters are more often associated with fetal ascites, severe anemia, and nonimmune hydrops.[48,49,50]Kudielka et al.[51] reported a case of PVB19 infection acquired during the second trimester of a mother with congenital spherocytosis. The infection resulted in severe hemolysis and failure of the reticulocytic response, resulting in anemia and aplastic crisis. High doses of IgG were administered to the primigravida, with laboratory test results returning to normal within 5 days of treatment. Ultimately, a healthy term infant was born.[52]The risk for fetal death from a household exposure to erythema infectiosum is between 0.4 and 1.5 percent, whereas the risk from a school exposure is between 0.2 and 0.75 percent. During community outbreaks, the risk ranges between 0.03 and 0.12 percent. Finally, the risk is between 0.01 and 0.03 percent with no known exposure. Pregnant women potentially exposed to PVB19 should be advised of the risks. Often, intrauterine PVB19 infection has no long-term effect on the fetus; however, abnormalities in neurodevelopmental status can be present in up to 30 percent of surviving fetuses with the growth and general health status remaining normal.[50,52]The risk for fetal death is approximately 2 to 9 percent. The risk for fetal death is probably greatest when infection occurs during the first half of pregnancy.[12,23,24]

Transient Aplastic Crisis

PVB19 has been identified as the primary causative agent of TAC. Community and household outbreaks have been associated with this syndrome.[12,15]Persons with hemoglobinopathies manifested by altered RBC production or turnover (e.g., sickle cell disease or thalassemia) may develop TAC with a reticulocytopenic anemia.[15,17]Initially, an acute exanthema characterized by symmetrical purpuric rashes or painful edema and erythema of the hands and feet develop. Other areas of the body are less affected. The exanthema may progress to purpuric papules and petechia that are sharply marginated on the wrists and ankles. PVB19 was the first virus discovered to be associated with the condition known as gloves and socks syndrome.[5]

Chronic Infection

Chronic infection has been demonstrated in immunocompromised persons, which may result in persistent anemia.[53]However, the pathogenesis of disease other than anemia is not clear. For example, rash and joint pains occur after the viremia has been cleared and may result from immune complex or other immune-mediated complications of infection. Chronic PVB19 infection has been demonstrated in patients with no known immune deficiency, without anemia, and with either no disease or various diseases including neuropathy, recurrent rash, and systemic vasculitis. The PVB19 virus persists in nonerythroid cells of some persons, but it is not known if this persistence causes disease. Viremia may be present for months to years after acute infection occurs.[13,17,54,55,56,53]Secondary infections have also been shown to occur in health adults, despite prior positive antibody tests.[57]

Association with Other Disease Entities

Radioactive in situ hybridization has confirmed the presence of PVB19 in endothelial cells of the myocardium within the veins, arteries, and arterioles in the presence of acute inflammatory cardiomyopathy.[58,59,60,61]The infection has also been reported in association with a variety of other diseases, including systemic vasculitis, idiopathic thrombocytopenia purpura, hepatitis, and hemophagocytic syndrome.[61]Although PVB19 replicates most efficiently in erythroid precursor cells, it is possible that abortive or low-efficiency infections occur in other cells and contribute to some of the disease.[62,63]However, a causative relationship between this viral infection and the previously mentioned diseases has not yet been demonstrated.[60,63,64,65,66]

Diagnosis

PVB19 Immunoglobulin M

PVB19 IgM antibodies targeting viral VP2 proteins develop after infection occurs in a nonimmune host. Serological tests for these antibodies are most commonly used to detect PVB19 infection in individuals with normal immune systems. When TAC occurs, IgM is present at the onset of symptoms. IgM titers begin to fall during the second month after the onset of illness and usually become negative within 4 to 6 months. A variety of assays for identifying IgM exist.[67,68]

Table 88-1 Immunity Status Based on Antibody Testing

Immunity Status	Immunoglobulin G	Immunoglobulin M
Susceptible host	Negative	Negative

Recent infection (past 7–10 days)	Negative	Positive
Recent infection (past 7–120 days)	Positive	Positive
Past infection	Positive	Negative

PVB19 Immunoglobulin G

Initially, IgM antibodies develop, followed by IgG antibodies a few days later. IgG antibodies are generally present within 2 to 3 weeks after infection and by the onset of rash in persons with erythema infectiosum. These antibodies (IgG) tend to persist long term and are thought to indicate the presence of protective immunity. Therefore, past infection is best detected by the presence of PVB19 IgG antibodies. A variety of assays have been developed for this purpose. Unlike IgM antibody assays, many of these have acceptable sensitivity and specificity.[67,68]Refer to Table 88-1 for interpretation of IgM and IgG antibodies.

PVB19 Antigen Detection

Antibody assays are often not helpful in detecting infection in immunosuppressed individuals or chronic infection in those who are immunologically normal. In these populations, it may be necessary to perform tests for viral detection; however, PVB19 is difficult to cultivate in vitro.[17]The most sensitive way to detect PVB19 virus is by isolating its DNA by direct hybridization or PCR amplification. Nucleic acid hybridization and PCR assays are the most sensitive methods and may be required in some individuals. However, these tests are less sensitive in individuals with low levels of viremia.[2,3,38]

Histological Identification

The presence of the PVB19 virus can also be suggested by histological changes, the most characteristic of which are large normoblasts (erythroid precursor cells) with marginated chromatin and eosinophilic nuclear inclusions. Parvovirus-like particles can be detected by electron microscopy in a variety of specimens. In situ hybridization or immunohistological studies can be used to confirm the presence of PVB19 in tissue or cells. These types of studies have been essential to the current understanding of the pathogenesis of PVB19 disease.

Management

Supportive

Approximately 20 percent of individuals who become infected with PVB19 do not develop symptoms. In some, a nonspecific illness may occur without the characteristic rash. The majority of cases require no treatment. For those who develop symptoms, supportive treatment may be offered, including antipyretics, analgesics, and antihistamines to help to control symptoms. Additionally, activity restriction and rest may be indicated.[30]In cases of myocarditis, while supportive measures may be used, these are often of a more critical nature, including pressors and possibly long-term use of a ventricular assist device to allow for recovery of the myocardium over time.[69,70,71]

Immunoglobulin G Intravenous Therapy

Prolonged illness or more severe illness may occur in immunocompromised individuals. Therefore, PVB19 should be considered in the differential diagnosis in the presence of reticulocytopenic anemia in persons receiving immunosuppressive therapy for cancer, leukemia, lymphoma, or tissue transplantation and those with HIV infection. Those with severe viremia may require IVIG therapy. This treatment usually results with reticulocytosis, an increase in hematocrit, and control of the viremia. However, the infection may not always be cured by IVIG, and additional courses may be required when anemia recurs.[19,41]However, IgG therapy is not without risk. There have been reports of myocardial infarction, acute renal failure, and less frequently, thrombotic events.[72]

Blood Transfusions

Individuals with TAC can rapidly develop severe anemia and may require supportive therapy, including blood transfusions.[2,15,17,43]

Infection Prevention and Control Measures

Hand Hygiene and Standard Precautions

Appropriate hygienic practices including adequate hand-washing practices, use of alcohol-based hand washes, and not sharing food and eating and drinking utensils should diminish the risk for acquiring PVB19 infection.[1,73]For all cases, Standard Precautions (respiratory hygiene and cough etiquette, hand hygiene, environmental cleaning) will minimize the transmission of respiratory pathogens in healthcare settings. The components of respiratory hygiene and cough etiquette include the following: covering the mouth and nose during coughing and sneezing, using tissues to contain respiratory secretions with prompt disposal into a nontouch receptacle, offering a surgical mask to persons who are coughing to decrease contamination of the surrounding environment, and turning the head away from others while maintaining spatial separation of at least 3 feet when coughing.[1]Therefore, all individuals should be instructed to cover their mouths and noses when coughing or sneezing and immediately discard soiled tissue followed by hand disinfection.[1,30]

Transmission-Based Precautions for Erythema Infectiosum

The virus cannot be isolated in the secretions of otherwise healthy individuals after the onset of erythema infectiosum rash, arthralgias, and arthritis. It is acceptable to use Standard Precautions after these symptoms develop. However, Droplet Precautions are indicated for certain hospitalized patients with PVB19 infection. Patients with transient aplastic or erythrocyte crisis should remain isolated for a full 7 days after admission. Viremic patients with an aplastic crisis, immunosuppression with chronic infection, and anemia should be isolated for the duration of the illness or hospitalization. These patients should not share rooms with pregnant women, those who may be pregnant, or immunocompromised individuals. Neonates with PVB19 infection should be placed in droplet isolation. Current guidelines for Isolation Precautions should be consulted for additional information regarding infection prevention practices for patients with PVB19 infection. In addition, the Centers for Disease Control and Prevention and Healthcare Infection Control Practices Advisory Committee's Guidelines for Infection Control in Healthcare Personnel (published in 1998) has a section on parvovirus considerations for healthcare personnel.[1,73]

Conclusions

PVB19, the agent of a human infection from the *Parvoviridae*family, is globally endemic, and infection is often asymptomatic. The disease process is most often acquired in childhood and may manifest with mild symptoms followed by a rash (erythema infectiosum). Transmission is frequently via the respiratory tract, but the virus may also be found in blood and blood products. Vertical transmission from mother to fetus can be devastating depending on gestational age at time of maternal infection. The PVB19 infection may be confused with other illnesses, and the agent has been implicated in other disease processes. Infection prevention measures include applying Standard Precautions coupled with Droplet Precautions to prevent transmission in healthcare settings.

Future Trends

DETECTION OF PVB19 IN DONATED BLOOD PRODUCTS

Real-Time Nucleic Acid Testing

A study was performed in Germany and Austria by Schmidt et al.[74]in which 2.8 million blood donations were screened for PVB19 using the nucleic acid testing (NAT) method. Blood containing neutralizing antibodies known as VP2 were found in donations containing less than 105 international units/mL. These units were thought to be safe, and they were released for use. These blood recipients are involved in a follow-up study of infectivity.[74]However, another study using the NAT method, cited at the U.S. Food and Drug Administration Nucleic Acid Testing Workshop in December 2001, found a high rate of false-positive results.[73]

Receptor-Mediated Hemagglutination

Wakamatsu et al.[75]screened blood donors using the receptor-mediated hemagglutination (RHA) method. This test is based on an interaction between PVB19 and the P antigen located on human erythrocytes. They concluded that large-scale screening of donated blood for PVB19 using a combination of RHA and RHA inhibition testing has high specificity and may be useful in screening donor units for PVB19.[75]

Health Council of the Netherlands

A committee of the Health Council of the Netherlands recommends a risk group approach for the administration of "big-virus safe" cellular blood products to patients with underlying hematological disease, pregnant women, and those with immunodeficiency. Big-virus safe blood products are those derived from a blood donor in whom IgG antibodies against PVB19 have been detected in two separate blood samples taken at least 6 months apart. Patients within a risk group may experience serious complications if infected with PVB19. Those patients not within a risk group may continue to receive cellular blood products pursuant to current safety criteria.[76]

Additional studies are needed to identify reliable testing methods for potentially infectious PVB19 in blood products.

Ultraviolet C Radiation

An effective method of increasing the safety of potentially PVB19 contaminated factor VIII concentrates, without losing coagulation activity, may include ultraviolet C radiation in the presence of catechins (including epigallocatechin gallate).[77]

Vaccine Development

There is currently no approved human vaccine for PVB19. A 2006 clinical randomized, placebo-controlled, double-blind clinical trial of the immunogenicity and safety of two dose levels of a recombinant human parvovirus B19 vaccine is evaluating the safety of study vaccine healthy parvovirus B19 seronegative adults and will verify that the vaccine produces immunity. The evaluation of the study may lead to development of commercially available PVB19 vaccine. However, currently a double-blind trial has been discontinued due to unexplained cutaneous events in 3 of 43 enrolled subjects.[76,78]

Abstract

Rabies is a zoonotic disease that is usually transmitted via virus-containing saliva from the bite of an infected animal. The virus infects the central nervous system, resulting in an acute, progressive, fatal encephalomyelitis. Although rabies in domestic animals has significantly decreased in the United States since the mid-20th century, rabies in terrestrial wildlife and bats in the United States and other developed countries, as well as canine rabies in developing countries, continues to present risk for human infections. Human infections can be prevented through avoiding exposure to rabid animals, pre-exposure rabies vaccination of individuals in high-risk occupations, and postexposure prophylaxis (vaccination and rabies immunoglobulin administration) for individuals with exposure with high risk for rabies virus transmission.

Key Concepts

- Rabies is a fatal viral infection transmitted primarily by bites of infected animals.
- Rabies infections in humans can be prevented by avoiding exposure and by using pre-exposure (vaccination) or postexposure (vaccination and rabies immunoglobulin) prophylaxis.
- Animal rabies control programs are effective in reducing the risk of human and animal infections.
- Rabies is a nationally notifiable disease.

Background

Rabies is a fatal viral disease of the central nervous system (CNS), causing acute, progressive encephalomyelitis that affects mammals, including humans. There are several variants of the virus, each of which has adapted to specific hosts—primarily bats and carnivorous mammals. In the United States, the main reservoirs of the virus are wildlife, including raccoons, skunks, foxes, and bats, which account for more than 90 percent of rabid animals reported.[1]With the advent of vigorous canine rabies control programs beginning in the 1940s, domestic dogs have been eliminated as a reservoir of rabies in the United States. This, combined with the development of effective biologics (vaccine and rabies immunoglobulin), has reduced the number of U.S. human deaths attributable to rabies to an annual average of one to two.[2]

Despite the successes seen in canine rabies control, rabies continues to be a disease of clinical and public health importance in the United States and abroad. Globally, there are 55,000 human rabies deaths each year, and dogs are the major infective host.[2]In the United States alone, approximately 20,000 to 40,000 persons receive postexposure prophylaxis (PEP) annually.[3]A variety of factors contribute to high levels of PEP administration in the United States: the significant epizootic of raccoon-variant rabies in raccoons and other terrestrial animals in the Eastern and Southeastern United States; the persistence of unvaccinated domestic animals; and the continued recognition of bats as a reservoir of rabies virus. The goal of this chapter is to provide a basic understanding of the clinical and epidemiological characteristics of rabies in order to aid the reader in making informed decisions during risk assessments for animal exposures and in the care of patients for whom rabies is in the differential diagnosis.

Basic Principles

Definitions related to rabies transmission are provided here.

*Bite contact:*any penetration of the skin by the teeth of an animal.

*Domestic animal:*a species of mammal that is accustomed to living in or about the habitation of man and is dependent on man for food or shelter, including but not limited to dogs, cats, ferrets, and livestock.

*Fluorescent antibody testing:*laboratory method used to assess animal tissue for evidence of rabies virus infection.

*Isolation:*confinement of an animal in a double-door, escape-proof enclosure; the animal is not removed from the enclosure at any time except for transport.

*Nonbite contact:*contamination of an abrasion, open wound, or mucous membrane with saliva or other potentially infectious material from an animal.

*Oral rabies vaccine (ORV):*used for the oral vaccination of wild animals against rabies; it consists of a vaccine-filled plastic pouch that is enclosed in fishmeal or directly coated with flavoring for use with raccoons, foxes, and coyotes. ORV is a live vaccinia virus-rabies glycoprotein vaccine, and its use is restricted to state- or federal-approved programs.

*Postexposure prophylaxis (PEP):*the administration of rabies vaccine and rabies immunoglobulin to individuals following an exposure with a high risk for transmission of rabies virus.

*Pre-exposure prophylaxis:*an abbreviated rabies vaccination schedule for individuals working in occupations associated with a high risk of exposure to rabies virus.

*Quarantine:*confinement of an animal by leash, an escape-proof enclosure, or another manner that ensures protection of the public's health. Note: The situations in which isolation or quarantine is applied vary from state to state and country to country.

*Rabies immunoglobulin (RIG):*in the United States, this is purified plasma from hyperimmune donors. RIG is usually administered at the site of exposure and quickly provides a short duration of passive immunity (21-day half-life).

*Rabies titer testing:*testing of serum from individuals who previously received rabies vaccine for the presence of rabies virus-neutralizing antibodies. Testing is generally limited to assess the requirement of booster vaccination for individuals in high-risk occupations.

*Rabies vaccine for humans:*in the United States, it is an inactivated virus vaccine that is administered intramuscularly (IM). By 7 to 9 days after vaccination, an active immune response is induced, resulting in the production of rabies virus-neutralizing antibodies that usually persists for at least 2 years.

Characteristics, Diagnosis, And Control

RABIES VIRUS AND TRANSMISSION

Rabies virus is a bullet-shaped, single-stranded RNA virus of the family Rhabdoviridae and the genus *Lyssavirus*; it is relatively labile because it is inactivated by desiccation and ultraviolet irradiation. Pathogenesis of the disease involves travel of the virus via the peripheral nerves to the CNS, causing encephalomyelitis. The disease is almost always fatal once symptoms appear. The most common mode of transmission of rabies virus is through the bite of an infected animal. The virus may be shed in the saliva of an infected animal for several days prior to the onset of symptoms and continues to shed throughout the course of illness. The incubation period in the victim may depend on the location of the bite, virus variant, infectious dose, and immune status. The incubation period can vary from days (e.g., from high viral load exposures to the head), to months or even years in rare cases (e.g., from low viral load exposures extremely distal to the head, i.e., feet or hands).

Nonbite exposures from terrestrial animals have rarely caused rabies. These exposures include contamination of an abrasion, open wound, or mucous membrane with saliva or other potentially infectious material, such as neural tissue from an infected animal. Other nonbite routes of transmission have been documented and include concentrated aerosol transmission and corneal and solid organ transplantation.[2,3,4]Petting a rabid animal or contact with blood, urine, or feces of a rabid animal are not considered exposures. Additionally, ingestion of raw meat of an infected animal is not considered exposure.

CLINICAL SIGNS IN HUMANS AND ANIMALS

Clinical signs of rabies vary by species—the most reliable signs in animals are behavioral changes and unexplained paralysis. There are two classic forms of rabies in animals: the furious form, in which aggression is pronounced and the animal may attack humans, other animals, or inanimate objects, and

the dumb form, in which there is minimal or no behavior change and partial paralysis predominates. A classic example of the dumb form of rabies is the dog with an inability to swallow or keep its mouth closed, mimicking the appearance of "something caught in its throat."

In humans, the first signs of rabies are usually nonspecific and may include fever, chills, sore throat, malaise, headache, and weakness; often there is paresthesia at or near the exposure site. The neurological phase follows with hyperactivity; behavior changes such as agitation, anxiety, or fear; and sometimes seizures. Hydrophobia is a classic sign of rabies in humans with fear exhibited at the sight of water or while drinking it; this is caused by severe spasms of the muscles involved in swallowing. Early paralysis associated with rabies in humans affects the bitten extremity or may be symmetric or diffuse. As the disease progresses, there is generalized paralysis, a deterioration of mental status, and finally coma. Rabies is a rapidly fatal disease with death occurring a few days after the onset of symptoms. Supportive therapy may prolong a patient's life, but death is almost always inevitable. Reports of humans or animals recovering from rabies are rare, and these individuals usually have severe neurologic sequelae.

BATS AND RABIES

Bats are increasingly implicated as important wildlife reservoirs for rabies variants transmitted to humans. There was a 21.7 percent increase in the number of rabid bats reported from 2011 to 2012. Currently, vaccination of bats is not considered feasible; therefore, emphasis is placed on public education and prevention.[1]From 1990 to 2007, a total of 34 naturally acquired bat-associated human cases of rabies were reported in the United States.[5]If a bat bites a person, it should be captured and tested for rabies. If the bat is not available for testing, PEP is recommended for all persons who have sustained bite, scratch, or mucous membrane exposures. Further, because bat bites can inflict limited injury and may be undetected, PEP is appropriate if there is reasonable probability that such contact occurred (e.g., a sleeping person awakens to find a bat in close proximity or an adult witnesses a bat in the room with a previously unattended child or a mentally disabled or intoxicated person).[6,7,8]The importance of capturing and testing any bat that has known or suspected human contact cannot be overemphasized.

OTHER WILD ANIMALS AND RABIES

Raccoons, skunks, and foxes are the most common reservoirs for rabies in the United States. Geographic ranges show that the raccoon is most prevalent along the East Coast, and the skunk and fox are more prevalent in the West and Midwest. Growing numbers of rabid mongooses have been reported in Puerto Rico. The canine rabies virus variant has been eliminated from the United States.[1]If a wild animal has bite or nonbite exposure contact with a human and the animal is available, it should be tested for rabies. If the animal tests positive or is not available for testing, PEP should be administered. Rodents (such as squirrels, hamsters, guinea pigs, gerbils, chipmunks, rats, and mice) and lagomorphs (rabbits and hares) are almost never found to be rabid, and exposures to them rarely require PEP. Groundhogs (woodchucks) account for the majority of rabies cases in rodents. Although rabies in these rodents is rare, risk assessment of human exposures to these species, and decisions regarding PEP administration, should include an evaluation of the prevalence of rabies in other terrestrial species (i.e., raccoons, skunks, foxes) in the geographic area of exposure. This information is available from local or state public health agencies.

MANAGEMENT OF RABIES IN ANIMALS

Animal vaccination programs are essential for the control and prevention of rabies. Dogs, cats, and ferrets should be vaccinated according to state laws and regulations. Other domestic animals at risk in rabies-endemic areas should be vaccinated if an approved vaccine is available. Following an exposure of an animal or human to a suspected rabid animal, the local health department should perform a risk assessment. This includes the epidemiology of rabies in the area (endemic reservoir hosts present; species of the exposing animal), a determination of type of exposure (i.e., bite versus nonbite exposure), circumstances of the exposure (i.e., provoked versus unprovoked), availability of the animal for quarantine or testing, and health and vaccination status of the animal.

The following guidelines are adapted from the *Compendium of Animal Rabies Prevention and Control, 2011*.[9]Dogs, cats, and ferrets currently vaccinated and exposed to a rabid animal should be revaccinated immediately, kept under the owner's control, and observed for 45 days. If not currently vaccinated, exposed domestic animals should be euthanized and tested. If the owner refuses to agree to euthanasia of the animal, it must be placed in strict isolation for 6 months and vaccinated immediately or 1 month prior to release from isolation to assure that the animal is vaccinated at the end of quarantine if it does not develop rabies. Healthy dogs, cats, and ferrets that bite humans should be quarantined for 10 days after the exposure. If the animal does not exhibit signs and symptoms consistent with rabies during the quarantine period, the animal can be released, and the bite victim is considered at no risk for exposure to rabies. If the animal exhibits signs and symptoms consistent with rabies during the 10-day quarantine, dies during the quarantine, or is a stray, it should be euthanized and tested. Animals unwanted by their owners may be held for the 10-day quarantine or euthanized and tested immediately. Unvaccinated livestock should be euthanized immediately if exposed to a rabid animal. Vaccinated livestock should be revaccinated with a USDA-approved vaccine. Direct transmission from one animal to another in a herd is unlikely; therefore, restrictions on the remainder of the herd are typically unnecessary. Consultation with local health department personnel is recommended for potential rabies exposure situations involving animals not discussed here.

RABIES TESTING OF ANIMALS

In the United States, rabies in both humans and animals has been a nationally notifiable condition since 1944.[10]Because rabies testing requires intact brain/brainstem, care should be taken in using appropriate methods of euthanasia if testing of suspect animals is warranted. Nevertheless, animals whose heads have been damaged (through trauma, decay, etc.) may still be appropriate for testing. The appropriate health department laboratory should be contacted before deciding to discard a damaged animal so that an accurate assessment can be made of the utility of testing.

Laboratories performing rabies testing generally receive animal heads, as the testing requires the removal of the brain from the cranium. In addition to receiving pre-exposure vaccinations, laboratory workers processing these tissues use personal protective equipment and appropriate engineering controls and follow enhanced safety practices to reduce their risk of exposure to rabies from the bone fragments, tissue, and fluid encountered during this process. A direct fluorescence antibody assay is the gold standard in the diagnosis of rabies.[9]Once the brain is removed, touch impression smears are made from several parts of the brain (brainstem, cerebellum, and hippocampus). These smears are stained with fluorescent-labeled antirabies antibodies and examined for intracytoplasmic inclusions. The standardized protocol (available at **http://www.cdc.gov/rabies/pdf/RabiesDFASPv2.pdf**) should be performed by a qualified laboratory that has been designated by the state or local health department.[9]

Histopathologic examination of tissues for Negri bodies has been performed historically, but this method lacks the sensitivity and specificity of fluorescent antibody testing of tissue and is no longer routinely

used. There are enhanced laboratory techniques available to determine the reservoir host from which the virus originated.

MANAGEMENT OF RABIES IN HUMANS

Rabies in humans is a preventable disease if treatment is begun prior to the manifestation of symptoms. The current recommended treatment regimen is given in *Use of a Reduced (4-Dose) Vaccine Schedule for Postexposure Prophylaxis to Prevent Human Rabies: Recommendations of the Advisory Committee on Immunization Practices*[11](summarized in Table 89-1). Treatment initially requires appropriate cleansing of the bite wound (if present), followed by intramuscular administration of human rabies vaccine on days 0 (the first day of vaccination), 3, 7, and 14. Immunosuppressed individuals require an additional dose of vaccine on day 28 and a postvaccination virus-neutralizing antibody titer to ensure acceptable antibody response.[11]Rabies immunoglobulin is also administered on day 0 at a dosage of 20 IU/kg body weight, with the full dose being infiltrated at the site of the bite if anatomically feasible. RIG should not be administered with the same needle or at the same site as the vaccine. The Advisory Committee on Immunization Practices (ACIP) also gives recommendations for pre-exposure vaccinations of individuals among high-risk groups, such as veterinarians, animal handlers, veterinary technicians, certain laboratory workers, and persons visiting foreign countries where canine rabies is endemic and access to adequate medical care might be limited. The pre-exposure vaccination regimen (Table 89-2)[5], [11]requires administration of vaccine on days 0, 7, and 21 or 28 (RIG is not administered as part of this regimen). Pre-exposure vaccinations may protect persons with unapparent exposures to rabies and persons whose PEP may be delayed; it eliminates the need for RIG, and it decreases the number of doses of PEP vaccine needed to two (days 0 and 3). Both pre-exposure vaccination and PEP can be administered during pregnancy if indicated.

If an animal cannot be found, but there is a potential that it will be, PEP may be postponed for a few days. Alternatively (if indicated by the risk assessment), PEP can be started and then discontinued when the animal is found to be healthy after 10 days from the exposure or tested and found negative for rabies. Initiation of PEP for suspected high-risk rabid animal exposures should not be delayed for the full 10 days with the expectation of finding the exposing animal.

In the event that an individual misses a treatment, rabies vaccine should be given as soon as possible and the regular treatment schedule resumed. People who began treatment for rabies overseas should be evaluated on a case-by-case basis. If the vaccine given in a foreign country is an unfamiliar one, discuss the issue with the state or local health department or the Centers for Disease Control and Prevention (CDC).

Serious adverse reactions to a rabies vaccine should be reported to the Vaccine Adverse Event Reporting System (see Supplemental Resources). Most reactions to modern vaccines are less serious than with previously available vaccines, and the vaccination regimen can be continued with management of the adverse reaction. For very serious reactions, consult with the local or state health department or the CDC to determine if vaccination should be continued.

Table 89-1 Rabies Postexposure Prophylaxis Schedule—United States, 2008

Vaccination Status	Treatment Regimen[a]

Not previously vaccinated	Wound cleansing	All postexposure prophylaxis should begin with immediate thorough cleansing of all wounds with soap and water. If available, a virucidal agent such as povidone-iodine solution should be used to irrigate the wounds.
	Rabies immuno-globulin (RIG)	Administer 20 IU/kg body weight. If anatomically feasible, the full dose globulin (RIG) should be infiltrated around the wound(s), and any remaining volume should be administered intramuscularly (IM) at an anatomical site distant from vaccine administration. Also, RIG should not be administered in the same syringe as vaccine. Because RIG might partially suppress active production of antibody, no more than the recommended dose should be given.
	Vaccine	Human diploid cell vaccine (HDCV) or purified chick embryo cell vaccine (PCECV) 1.0 mL, IM (deltoid area[c]), one each on days 0[d], 3, 7, 14, and 28.
Previously vaccinated[b]	Wound cleansing	All postexposure prophylaxis should begin with immediate thorough cleansing of all wounds with soap and water. If available, a virucidal agent such as povidone-iodine solution should be used to irrigate the wounds.
	RIG	RIG should not be administered.
	Vaccine	HDCV or PCECV 1.0 mL, IM (deltoid area[c]), one each on days 0[d]and 3.

[a]These regimens are applicable for all age groups, including children.
[b]Any person with a history of a complete pre-exposure or postexposure vaccination regimen with HDCV, PCECV, or rabies vaccine adsorbed, or previous vaccination with any other type of rabies vaccine and a documented history of antibody response to the prior vaccination.
[c]The deltoid area is the only acceptable site of vaccination for adults and older children. For younger children, the outer aspect of the thigh can be used. Vaccine should never be administered in the gluteal area.
[d]Day 0 is the day the first dose of vaccine is administered.
From Manning SE, Rupprecht CE, Fishbein D, et al. Human rabies prevention—United States, 2008: recommendations of the Advisory Committee on Immunization Practices. *MMWR Recomm Rep*2008;57(RR-3):1–28. Available at: **http://www.cdc.gov/mmwr/preview/mmwrhtml/rr5703a1.htm**.

Following pre-exposure vaccination, an individual at frequent risk of exposure should be tested for presence of rabies-neutralizing antibodies every 2 years. Booster vaccinations should be administered if the antibody level falls below acceptable levels—complete virus neutralization at a 1:5 serum dilution by the rapid fluorescent focus inhibition test (RFFIT). High-risk individuals working with live rabies virus in research facilities or vaccine production facilities should have a rabies antibody titer performed every 6 months. State or local health departments have information regarding laboratories available for rabies antibody titer determination.

Table 89-2 Rabies Pre-exposure Prophylaxis Schedule—United States, 2008

Type of Vaccination	Route	Regimen

Primary	Intramuscular	Human diploid cell vaccine (HDCV) or purified chick embryo cell vaccine (PCECV); 1.0 mL (deltoid area), one each on days 0,[a]7, and 21 or 28
Booster[b]	Intramuscular	HDCV or PCECV; 1.0 mL (deltoid area), day 0 only

[a]Day 0 is the day the first dose of vaccine is administered.
[b]Persons in the continuous-risk category should have a serum sample tested for rabies virus-neutralizing antibody every 6 months, and persons in the frequent-risk category should be tested every 2 years. An intramuscular booster dose of vaccine should be administered if the serum titer falls to maintain a value of at least complete neutralization at a 1:5 serum dilution by rapid fluorescent focus inhibition test.
From Manning SE, Rupprecht CE, Fishbein D, et al. Human rabies prevention—United States, 2008: recommendations of the Advisory Committee on Immunization Practices. *MMWR Recomm Rep*2008;57(RR-3):1–28. Available at:**http://www.cdc.gov/mmwr/preview/mmwrhtml/rr5703a1.htm**.

For suspected cases of human rabies, public health authorities should be contacted immediately to assist in obtaining the most current testing and treatment protocols. CDC infection prevention recommendations for the care of patients with known or suspected rabies do not supersede the utilization of Standard Precautions.[5]Although confirmed person-to-person transmission of rabies has not been documented, it is a theoretical possibility. Several authors have recommended that healthcare personnel use Contact Precautions including wearing mouth and eye protection while caring for patients to protect mucous membranes from exposure to contaminated saliva.[12,13]In addition, PEP has been recommended for healthcare personnel with nonintact skin or mucous membrane exposure to potentially infective saliva.[13,14]Submission of specimens from patients suspected of being infected with rabies virus should be coordinated with the local or state health department and the CDC. Instructions for specimen collection and handling, and the forms required for submission, are available from the CDC rabies website (see Supplemental Resources).

PREVENTION AND CONTROL OF RABIES

Prevention and control of rabies involves the efforts of state and local officials as well as the entire community. Vaccination programs, leash laws, licensing, stray animal control, bite reporting, prompt treatment, pre-exposure vaccination, and proper risk assessments are essential to the prevention and control of rabies. Education of the public is also essential and should include the following recommendations: limit exposure to wild or stray animals, do not keep wild animals as pets, and maintain up-to-date vaccinations for pets.[5]The use of oral bait containing rabies vaccine to immunize wildlife animal reservoirs, such as foxes, raccoons, and coyotes, has proven successful in rabies control in certain communities. Because currently used oral rabies vaccine is a live, recombinant vaccinia-rabies glycoprotein virus, human exposure to the vaccine can result in vaccinia infection, as has been recently documented in one individual with no serious sequelae.[15]

Conclusions

Despite success seen in rabies control in domestic animals in developed countries, rabies continues to be an issue of significant clinical and public health importance. The annual number of human cases observed in the United States is low, no doubt due to the diligence of clinical and public health practitioners investigating and providing appropriate follow-up for potential high-risk exposures. Although not a medical emergency, rabies exposure is a medical urgency, requiring prompt attention but allowing for ample time to investigate the exposure situation and determine the most appropriate management course to take.

Future Trends

Human rabies is fatal in almost all cases; there have been countless failed attempts to treat human rabies cases. In 2004, a 15-year-old girl survived rabies infection without the use of any rabies vaccine or immunoglobulin by induction of a coma, a brain-sparing procedure that allowed for natural immune responses to overcome the infection.[16]This protocol (Milwaukee Protocol) has been attempted in other patients without success but is constantly being refined and may have potential in patients in whom rabies infection is suspected early on in the clinical diagnostic process.

Currently in the United States, RIG is a product of human hyperimmune serum; it is expensive and available in limited quantities. To eliminate the need for human donors, researchers have developed monoclonal antibody cocktails to replace the use of RIG. At least one commercial company has completed initial safety studies in humans of its product.[17]Human testing is ongoing and may soon yield a product that can be produced in unlimited amounts without the disadvantages associated with a human hyperimmune serum product. An initial safety and tolerability study appears promising.[18]

The CDC has developed a direct rabies immunohistochemical test (dRIT) that has been used for active rabies surveillance studies by the U.S. Department of Agriculture, Wildlife Services, and in other field studies in Africa. It has acceptable sensitivity and specificity for rabies screening tests and high concordance with the currently accepted direct fluorescent antibody test.[19]The advantages of this test are that it can be used on preserved tissue samples, does not require a fluorescence microscope (only a light microscope is required), can be performed under less-than-ideal laboratory conditions, and can be performed by personnel with only dRIT-specific laboratory training.

There are ongoing efforts to contain the spread and control potential "point-source" outbreaks of raccoon-variant rabies from the currently delineated endemic zone in the United States. The U.S. Department of Agriculture, Animal Plant and Health Inspection Service, Wildlife Services is the lead agency in this prevention and control activity.[20]Aerial dropping of ORV has been used in an attempt to establish an immune barrier on the western edge of this zone, at the expenditure of significant federal, state, and local resources. A variety of studies have evaluated factors, including the area to cover with bait, the density of bait dropped in an area, and the number of times to perform the drops. Investigations continue to determine the most effective strategies (financially and scientifically) to maintain this immune barrier, as well as how aerial ORV drops can be used in point-source outbreak control.

International Perspective

Special circumstances to consider internationally center on two areas. First, the level of endemic canine rabies is high in many developing countries. This results in increased risk of human infections not only for citizens of those countries but also for travelers to these countries (consult the CDC rabies website; see Supplemental Resources). If warranted for travelers to developing countries, pre-exposure vaccination should be initiated far enough in advance of travel to allow for completion of the series. Second, the formulation of rabies vaccine and RIG varies in different parts of the world.[2,3] Because these differences can affect the dosing, route of administration, and occurrence of side effects, consultation with appropriate public health officials should occur in situations where biologics from alternative or multiple sources may have to be utilized.

APIC TEXT OF INFECTION CONTROL AND EPIDEMIOLOGY

Respiratory Syncytial Virus

Author(s): Joan Godich, BSN, RN

Published: October 2, 2014

Abstract

Respiratory syncytial virus is one of the most important causes of respiratory tract infection in infants and the elderly worldwide. Transmitted by direct and indirect contact, respiratory syncytial virus spreads as readily in the hospital as it does in the community, making healthcare-associated infection common. Respiratory syncytial virus is a major preventable healthcare-associated infection with frequent outbreaks that can lead to high mortality rates in healthcare facilities. Proper infection prevention measures, including hand hygiene, standard and contact precautions, cohorting, and rapid diagnostic techniques, are critical in controlling the spread of respiratory syncytial virus in healthcare facilities and establishing a culture of patient and employee safety. Timely implementation of standard infection control measures will minimize its medical and economic impact.

Key Concepts

- Respiratory syncytial virus is an RNA virus and a member of the Paramyxovirus family. Currently there are two serotypes: A and B.
- Respiratory syncytial virus is one of the leading causes of respiratory illness in infants, young children, and the elderly.
- Infections with respiratory syncytial virus are seasonal with predictable community outbreaks occurring in the winter and spring. In temperate climates, infections may appear year-round.
- Immunity to respiratory syncytial virus is short lived, and repeat (but milder) infections are common.
- Clinical syndromes in infants and children include upper respiratory infection, bronchiolitis, pneumonia, croup (rare), otitis media, and sudden infant death syndrome. Lower respiratory infections are also seen in adults.

- Respiratory syncytial virus is spread by respiratory secretions, and transmission is through direct or indirect contact with nasal droplets from infected individuals or by indirect contact with contaminated hands or fomites.
- Meticulous hand hygiene, contact precautions, and rapid detection are paramount to reducing morbidity and mortality associated with these common viral infections.

Background

Respiratory syncytial virus (RSV) causes lower respiratory infections in infants and young children worldwide.[1]The Centers for Disease Control and Prevention (CDC) reports that during the period 1997 to 2006, approximately 132,000 to 172,000 children under the age of 5 years were hospitalized for RSV infection annually in the United States. First isolated from chimpanzees in 1956,[2]RSV quickly became recognized as an important cause of lower respiratory tract infections in infants.[3]Despite reports in the 1960s of RSV infection in adults with pneumonia, the seriousness of RSV infection in adults and the elderly was not appreciated for nearly three decades.[4]

Across ages and global divides, the attack rate of RSV infection is very high. Although it is a seasonal pathogen, it infects up to 50 percent of children in the first year of life and 90 percent by 2 years of age. Natural infection does not confer full immunity, and reinfection throughout life is common and is usually associated with milder disease.

RSV infection is generally benign in the immunocompetent child or adult; however, factors that increase the risk of severe RSV lower respiratory tract illness include patients at the extremes of age, such as premature neonates or the elderly, as well as patients with other risk factors such as chronic lung disease (CLD), congenital heart disease (CHD), or compromised immunity.

The purpose of this chapter is to review the role of RSV as a healthcare-associated infection (HAI). The focus will include new developments in understanding of seasonal and geographic parameters in RSV transmission, review the effectiveness of various methods aimed at preventing transmission, and highlight new and emerging diagnostic, therapeutic, and preventive measures for RSV.

Basic Principles

RSV is a member of the family Paramyxoviridae, genus *Pneumovirus*.[5]The genome is composed of a single-stranded, nonsegmented genome that encodes 11 viral proteins. The envelope contains a fusion (F) protein and an attachment (G) protein but no hemagglutinin or neuraminidase. Two subgroups of RSV, A and B, have been recognized based on antigenic variations in structural proteins. Heterogeneity among both group A and B viruses has also been noted based on immunologic reactivity with monoclonal antibodies and nucleotide sequence determinations. Both subgroups of RSV are commonly isolated; however, group A viruses predominate.[6]

RSV is an infectious agent that is transmitted by direct and indirect contact. The spread of RSV occurs as readily in the hospital as it does in the community, making it an HAI.[7]Proper infection prevention measures, including hand hygiene, contact precautions, cohorting, and rapid diagnostic techniques, are critical in controlling the spread of RSV in hospitals and curtailing its medical and economic impact.

Respiratory Syncytial Virus

EPIDEMIOLOGY

In temperate climates, annual community outbreaks of RSV infections usually occur during late fall, winter, and early spring. The timing and severity of outbreaks in a community vary somewhat from year to year. In tropical climates, the pattern of RSV infection is different. In countries near the equator, the virus is detected year-round. As one moves away from the equator, there is a seasonal association with decrease in temperature both north and south of the equator. Rainfall, however, seems to have a positive association with RSV outbreaks north of the equator and a negative association south of the equator. Epidemics start in coastal areas and move inland with similar strains of RSV appearing in disparate geographic loci. This phenomenon has led some researchers to hypothesize that RSV is present year-round, causing epidemics when the appropriate environmental and host factors are present.

ENVIRONMENTAL FACTORS

RSV is quickly inactivated by ether, chloroform, detergents, freezing at -20°C, heating at 55°C, and low pH conditions. On hands, RSV remains infective for less than 1 hour. On environmental surfaces, RSV may survive up to 30 hours depending on humidity.[7]Other environmental settings implicated in RSV transmission include crowding, day care attendance, exposure to environmental air pollutants such as smoke, and large family size.[8]These environmental aspects are risk factors for RSV infection and are considered in decisions to administer immunoprophylaxis.[9]Some of these conditions, such as crowding, are also climate dependent and may play a role in the epidemiology and seasonal patterns of RSV infection.

HOST FACTORS

Host factors increase the risk of acquiring RSV infection and affect the severity the infection has on the exposed individual. Immunocompromised children and adults, as well as patients with chronic heart disease and lung disease, suffer higher mortality rates from RSV.[10]Immunocompromised persons include premature neonates, the elderly, patients with primary and secondary immunodeficiency, transplant recipients, and cancer patients receiving chemotherapy. Patients with chronic heart and lung conditions include those with bronchopulmonary dysplasia, cystic fibrosis, and CHD. Compromise of the immune system as well as the organ systems contribute to the pathogenesis of RSV disease.

MODE OF TRANSMISSION

Transmission of RSV is by direct contact with infected patients via large-particle droplets that generally do not traverse more than 3 feet. Indirect transmission can occur from hands or fomites that are contaminated with RSV. In a classic study on RSV transmission, Hall and Douglas demonstrated that direct contact plays a critical role.[11]Volunteers were assigned to one of three categories in handling infants with RSV: (1) routine care where contact was not limited, (2) limited contact where exposure to the environment was not restricted, and (3) no contact where there was no direct contact and the caregiver sat next to the crib. Five out of seven (71 percent) of the full contact, four of the 10 (40 percent) with limited contact, and none of the 14 (0 percent) no-contact caregivers became infected with RSV.[11]Transmission is also related to the amount of virus secreted by the infectious host. Infants and

immunocompromised persons shed more virus than do immunocompetent persons, and they commonly serve as reservoirs for RSV infections.

PATHOGENESIS

Inoculation of RSV occurs most often through the eyes, nose, or mouth. Once exposed, the incubation period ranges from 2 to 8 days. The exact mechanism of virus spread down the respiratory tract is not known. Spread may be from cell to cell or by microaspiration of secretions. The virus is contained in the respiratory tract, however, and cannot be cultured from the blood of immunocompetent individuals.[12] In the respiratory tract, the fusion protein binds to the respiratory epithelium. Direct cytopathic changes result in hyperplasia and squamous metaplasia with desquamation. An infiltrate of mononuclear cells and polymorphonuclear cells is seen. The clinical picture of bronchiolitis results from obstruction of small airways, mucous secretion, and syncytium formation. Pneumonia, hyperinflation, consolidation, bronchoconstriction, and hemorrhage can occur.

CLINICAL FEATURES

The initial and most common presentation of RSV is an upper respiratory tract infection including sneezing, rhinorrhea, nasal congestion, cough, and often fever. Progression to lower-tract disease may result in bronchiolitis, tracheobronchitis, and pneumonia. Exacerbation of underlying reactive airway disease, chronic lung disease, and other conditions that cause cardiopulmonary compromise is common. Chest radiographs may reveal hyperinflation, peribronchial cuffing, consolidation, or atelectasis. Hypoxemia and apnea are often seen in infants with RSV and are a common reason for hospitalization and monitoring. Although most patients recover from RSV in 1 to 2 weeks, respiratory failure and death can occur, especially in the immunocompromised and patients with underlying cardiopulmonary disease.

DIAGNOSIS

Laboratory diagnostic tests for RSV infection include antigen detection, culture, and amplified nucleic acid methods. Each has strengths and weaknesses that must be recognized in deciding which test methods to use in a particular clinical setting.

Accurate test results for each of these methods depend on the quality of patient specimen submitted to the laboratory. Common methods of collecting upper respiratory specimens include nasopharyngeal swabs, washes, and aspirates. Comparative studies have generally shown nasopharyngeal aspirates to be superior to swabs.[13] More cellular elements in a specimen maximize the chance of rapidly detecting respiratory viruses no matter which test method is used. Serologic diagnosis of RSV is rarely clinically useful.

The most rapid test methods are usually solid-phase immunoassays for detecting RSV antigens in respiratory tract secretions. An expanding selection of these commercial U.S. Food and Drug Administration (FDA)–approved tests has become available because of the clinical and economic importance of rapid diagnosis of RSV for infection control purposes. These tests are relatively simple and inexpensive, and they can be completed in approximately 30 minutes with minimal personnel training and expertise. Virus particles need not be viable to be detected. The disadvantage of the immunoassays is relatively poor analytic performance, particularly low sensitivity. In some comparisons, RSV enzyme immunoassay has been found to be less than 60 percent sensitive, in contrast to claims in package inserts.

In April 2012, the FDA approved labeling changes (Warnings and Precautions) for Synagis (palivizumab) injection regarding RSV diagnostic test interferences:

Palivizumab may interfere with immunological-based RSV diagnostic tests such as some antigen detection-based assays. In addition, palivizumab inhibits virus replication in cell culture and therefore may also interfere with viral culture assays. Palivizumab does not interfere with reverse transcriptase-polymerase chain reaction based assays. Assay I interference could lead to false-negative RSV diagnostic test results. Therefore, diagnostic test results, when obtained, should be used in conjunction with clinical findings to guide medical decisions.[14]

RSV antigens can also be detected by staining respiratory epithelial cells with fluorescein isothiocyanate (FITC)–conjugated anti-RSV antibodies (direct fluorescent antibody test, or DFA) and examining with fluorescent microscopy. Analyte-specific reagents are commercially available and relatively inexpensive. This test requires approximately 1 hour, and interpretation is best performed by highly skilled and experienced personnel. RSV DFA can be slightly more sensitive than isolation in culture, and viral viability is not required. This is the only method that allows direct evaluation of specimen quality (cellularity).

Isolation in culture is considered the gold standard of laboratory RSV diagnosis, even though the virus is relatively labile and sensitive to transport conditions. Culture of RSV from respiratory specimens can be performed in shell vials with results available after 48 hours of incubation. Shell vial cultures may be backed up with traditional culture in a variety of cell types, which can detect other respiratory viruses in addition to RSV. Detection of RSV in traditional cell cultures can be problematic because typical cytopathic effect may not be evident. Experienced laboratory personnel are required to interpret cytopathic effect, and time to results may be as long as 10 days.

At least one reverse transcription polymerase chain reaction (RT-PCR) kit is available for RSV and additional respiratory viruses.[15]In comparative studies, sensitivity of RT-PCR for RSV is greater than culture and/or DFA, though at present it has limited availability and tends to be more expensive. Specificity of RT-PCR is difficult to determine because there is not an equally sensitive standard for comparison, except perhaps serology combined with DFA and culture.

Once RSV is identified in the patient population, presumptive diagnosis of RSV infection cases is sometimes used for infection prevention purposes in subsequent similar cases. This saves the cost of laboratory testing unless it is needed to determine cessation of viral shedding.

TREATMENT

The mainstay treatment of RSV is supportive care; hydration, oxygenation, and mechanical ventilation may be required. Ribavirin, an antiviral agent with activity against RSV, is approved for treatment of severe RSV infections in hospitalized infants and young children. However, its use is controversial due to the requirement for aerosol administration, the potential for toxicity among exposed healthcare personnel, and questionable efficacy.[16]

PREVENTION

To date, no vaccine is available for active immunoprophylaxis of RSV infection. Only one product is available for passive immunoprophylaxis: palivizumab (marketed under the name Synagis). Palivizumab,a humanized mouse monoclonal antibody, is the only agent approved by the FDA for prevention of RSV disease in high-risk children (i.e., younger than 24 months with CLD requiring medical therapy (e.g., diuretics, supplemental oxygen, bronchodilators, or steroids), as well as children under 24 months with a history of premature birth. Premature birth is strictly defined as less than 35 weeks' gestation; however, children less than 32 weeks' gestation receive priority in the cost-benefit

equation of immunoprophylaxis. Children between 32 weeks' and 35 weeks' gestation should be considered for prophylaxis if two or more environmental and clinical risk factors are present: childcare attendance, school-aged siblings, exposure to environmental pollutants, congenital abnormalities of the airways, or severe neuromuscular disease.

Every month during the RSV season, palivizumab is given at a dose of 15 mg/kg intramuscularly. The American Academy of Pediatrics' recommendations include considering the use of immunoprophylaxis with palivizumab in patients with CHD if they are under 24 months of age and receiving medication to control congestive heart failure, have moderate to severe pulmonary hypertension, or have cyanotic heart disease. It is worth noting, however, that monoclonal antibody of palivizumab only binds the fusion protein of RSV and does nothing to prevent infection with other viruses.

Respiratory syncytial virus immune globulin intravenous (RSV-IGIV), previously used for prophylaxis, is no longer available.

Despite passive immunity, breakthrough RSV infections occur. To prevent these and all RSV infections, infection control measures cannot be overemphasized. These include proper hand hygiene techniques (using soap and water or alcohol-based hand sanitizer agents), contact precautions including gloves and gowns when having contact with the patient, and cohorting of patients; these are critical infection control practices to control the spread of RSV. Because the consequences of RSV infection can be devastating in immunocompromised patients, particularly neonates and stem cell transplant recipients, additional infection control measures have been advocated for these patient populations: wearing a surgical mask when in the room, droplet precautions (wearing a surgical mask when within 3 feet of the patient), prohibiting symptomatic visitor as well as healthcare worker contact with patients, and prohibiting children under 12 years of age from visiting. Methods involving the use of masks and respiratory precautions likely have more to do with the awareness of RSV and subsequent care with contact precautions rather than prevention of spread via the respiratory route.

FINANCIAL AND COST-BENEFIT ISSUES

Each clinical setting must determine its lowest cost-benefit management program for RSV infection. Important parameters include (1) risk factors and demographics of patient population, (2) cost of preventive measures, (3) cost of testing/screening methods, (4) cost of treatment measures, and (5) cost of disease (hospital stay, days off work or school, cost of secondary complications) to index patient and secondary cases, including healthcare personnel.

When effective vaccines become available, dollars spent on prevention by vaccine will probably provide the most benefit. The current method of prevention by passive immunoprophylaxis for high-risk patients remains costly and is offered only during the period when patients are most likely to be exposed.

Cost-benefit of laboratory testing/screening methods depends partly on the cost of providing the tests and partly on the costs averted by testing/screening. In many clinical inpatient settings, testing is used for cohorting to avoid nosocomial transmission because specific antiviral treatment is rarely administered. Some settings have opted to minimize laboratory testing and instead cohort by risk factors and symptoms. If a "test of cure" is used to release RSV-infected patients from isolation, the laboratory test chosen must be sufficiently sensitive to determine that viral shedding has ceased (thus excluding immunoassays) and sufficiently specific to avoid keeping patients in isolation needlessly. Immunosuppressed patients may shed viable RSV for months after initial infection. Traditional culture methodology for detection would add 10 additional days of isolation before results were available, but shell vial testing adds only 2 days. There are insufficient data to know whether antigen detection tests or RT-PCR remain positive after viable virus shedding has ceased, complicating the decision process.

Conclusions

RSV is an important respiratory pathogen worldwide, especially among the very young, immunocompromised persons, and the elderly. The mode of transmission and high-attack rate make RSV an important nosocomial pathogen, necessitating rapid diagnosis and timely implementation of infection prevention measures. Antiviral treatment has not been of marked value, whereas passive immunization with palivizumab has had a significant impact on RSV morbidity and mortality. Prevention strategies are critical for disease management, whereas supportive and symptomatic management remain the mainstay of treatment. Research continues on the development of several different types of vaccines and an enhanced-potency humanized RSV monoclonal antibody. Active immunization is in development and shows promise for curtailing the impact of RSV disease in the future.

Future Trends

Early studies with RSV vaccines were disappointing in that an increase in the severity of disease was observed in vaccine recipients.[17, 18] This phenomenon, and the fact that attack and case morbidity rates are high in infants under 6 months of age (when maternal antibody is still present), has led to the concern that the humoral immune response may be involved in disease progression rather than protection. However, subsequent studies have found that higher maternal antibody levels are protective against RSV disease[16,19] and that passive immunity with palivizumab is efficacious. These findings have renewed interest and hope in the development of an RSV vaccine.

For more than 50 years, researchers have been working on developing a vaccine for RSV. Current RSV vaccine strategies include the following vaccine development approaches: (1) attenuating the virus or (2) using recombinant technology to present viral antigens, often in the context of a replication-competent or replication-incompetent vector.

A number of attenuated RSV vaccines have now been tested clinically. The development of live-attenuated vaccines presents significant challenges. A concern is that viruses with compensatory mutations in the live-attenuated vaccines may associate with reversion to pathogenic phenotypes and lead to increased frequencies of adverse reactions *in vivo*. Manufacturing and distribution present difficulties due to the fact that the virus is sensitive to temperature changes. Also, attenuated strains are difficult to propagate to high titers.

At this time, there is greater flexibility in recombinant technology. This is true for the RSV antigen(s) and in the ways in which the antigen is expressed. Because each is capable of eliciting neutralizing antibodies and T-cell responses, the major target antigens of recombinant vaccine technology are RSV G and F. Additionally, reverse genetics can serve as delivery systems for RSV antigens. The RSV vaccine field today has a variety of new concepts and vectors, and there are currently a number of recombinant vaccines in preclinical testing stages.[20]

International Perspective

The international impact of RSV is significant. RSV is the most frequent reason that children in developed countries are hospitalized during the winter months. In 2005, 33 million new cases of RSV infection occurred in children under age 5, including more than 3 million severe cases that required

hospitalization. Each year in developing countries, RSV infection contributes to the mortality of an estimated 66,000 to 199,000 children. In the United States, an estimated 10,000 RSV-associated deaths occur annually among adults over 65. There is no worldwide estimate of RSV in the elderly.[21]

Discrepancy exists among developed and developing countries, as well as between the developed and developing world. For undetermined reasons, hospitalization rates even among industrialized nations vary. In 2004, the World Health Organization (WHO) published results of a study that assessed the burden of RSV-associated lower respiratory infection in four developing countries: Indonesia, Mozambique, Nigeria, and South Africa. Study findings demonstrated that RSV contributed to a substantial but variable burden of lower respiratory infection in children under 5 years of age.[22]

Mortality rates of RSV are low in both the developed and developing world but vary significantly among studies; case fatality rates range from 0 to 12 percent with an overall trend to higher mortality in developing countries.[23]The impact of RSV globally was so significant that in 1995 WHO declared RSV vaccine development one of the top priorities of the Global Programme of Vaccines.[24]

Abstract

The first part of this chapter covers sexually transmitted diseases. The second part of the chapter is devoted to gynecology. Many changes to the recommendations for prevention, diagnosis, and treatment of sexually transmitted diseases have recently been published. Education and counseling previously were recommended for patients with human papillomavirus and herpes simplex virus. The recommendations for human papillomavirus have been updated. Chlamydia screening recommendations have been updated. New tests are now available specifically for diagnosing human papillomavirus. Two vaccines for preventing the reduction of the sequelae of human papillomavirus infection are now available. Guidelines for the treatment of herpes simplex virus, scabies, pubic lice, and bacterial vaginosis have been revised. Cephalosporin and quinolone-resistant Neisseria gonorrhoeae*have become more prevalent in the United States, prompting new treatment recommendations. The diagnosis of gonococcal and chlamydial infections has improved with new analytical procedures. The gynecology section of this chapter emphasizes the impact of vaginal flora on postoperative infections and procedure-specific risks.*

Key Concepts

SEXUALLY TRANSMITTED DISEASES

- More cases of genital *Chlamydia trachomatis*infections are being reported, likely reflecting more screening and improved tests. Perinatal infections may result in conjunctivitis and pneumonia in newborns. The most serious sequelae of *C. trachomatis*in women include pelvic inflammatory disease, ectopic pregnancy, infertility, and pelvic pain syndrome. In men, sequelae include epididymitis, prostatitis, proctitis, proctocolitis, and Reiter syndrome. Sexually active adolescent women should be

screened at least annually, even if symptoms are not present. Annual screening of all sexually active women 20 to 25 years of age is also recommended, as is screening of older women with risk factors (i.e., those with new or multiple sex partners).

- Overall, rates of gonorrhea decreased in the United States from the 1970s to 1997 but have since increased. As with chlamydia, rates of gonorrhea are particularly high in the 15-to-24-year-old group. In men, rates are highest in the 20-to-29-year-old group. The incidence among men who have sex with men has increased dramatically. The dominant risk factor for acquiring gonorrhea is sexual intercourse with an infected partner. Pregnant women should be screened and treated for gonorrhea before delivery.
- Patients infected with *N. gonorrhoeae*are often coinfected with *C. trachomatis*. This has led to the recommendation that patients treated for gonococcal infections also be treated routinely with a regimen effective against uncomplicated *C. trachomatis*infection.
- Cephalosporin and quinolone-resistant *N. gonorrhoeae*have increased in prevalence and have become more common throughout the United States. As a result, quinolones are no longer recommended for the treatment of *N. gonorrhoeae*infections.
- Certain types of human papillomavirus are causing genital and anal warts. Other human papillomavirus types in the anogenital region have been strongly associated with cervical tumors. This is the most common sexually transmitted viral disease in the United States. Most human papillomavirus infections are asymptomatic, subclinical, or unrecognized. Treatment may reduce, but does not eliminate, the risk of transmission. Two human papillomavirus vaccines are available. Cervarix is a bivalent vaccine and Gardasil is a quadrivalent vaccine. Gardasil and Cervarix are recommended for use in females between 9 and 26 years of age and are recommended as a routine vaccination for girls 11 to 12 years of age. Gardasil can also be used to vaccinate males in this age range. Receipt of the vaccine or the presence of genital warts is not an indication for a change in the frequency of Papanicolaou tests or for cervical colposcopy.
- *Herpesvirus hominis*is an alternative name for herpes simplex virus. Herpes simplex virus type 1 (HSV-1) is transmitted primarily by contact with oral secretions and herpes simplex virus type 2 (HSV-2) by contact with genital secretions. Most people infected with HSV-2 have not had the diagnosis. The primary infection has a mean duration of 12 days and may be associated with a fever, malaise, anorexia, and tender bilateral inguinal adenopathy. Approximately two thirds of the patients have subsequent, usually milder recurrences. The diagnosis of genital herpes should be confirmed by laboratory testing. Complications and sequelae of genital herpes can include neuralgia, meningitis, ascending myelitis, urethral stricture, urinary retention, and secondary bacterial infection. The virus from an active genital infection may be transmitted during vaginal delivery, causing neonatal herpes infection, which can range from a mild localized presentation to a fatal disseminated infection. There is no known cure for genital herpes, though systemic antiviral drugs partially control the symptoms and signs of herpes episodes.
- Chancroid is worldwide in distribution and caused by the bacterium *Haemophilus ducreyi*. In the United States, chancroid usually occurs in outbreaks but is endemic in some areas. The prevalence of chancroid is decreasing worldwide and in the United States. An estimated 10 percent of people who acquire chancroid in the United States are coinfected with HSV or *Treponema pallidum*. That percentage is higher among those outside the United States. Chancroid is most frequently found in uncircumcised non-Caucasian men. Women account for only 10 percent of reported cases. Men frequently present with one ulcer, whereas women frequently have multiple lesions. The lesions are generally confined to the genital area and perineum. There is no asymptomatic carrier state. All patients should be tested for human immunodeficiency virus at the time of diagnosis, given that chancroid has been associated with an increased risk of heterosexual HIV transmission.

- Donovanosis, caused by *Klebsiella*(formerly *Calymmatobacterium*) *granulomatis*, is a genital ulcerative disease seen more commonly in tropical and developing areas than in the United States. Wounds caused by donovanosis can be complicated by secondary infection and may lead to lymphedema.
- *Phthirus pubis*(pubic or crab louse) often afflicts persons with poor hygiene, communal lifestyles, and multiple sex partners. Transmission occurs primarily through intimate physical or sexual contact. Symptoms range from slight discomfort to severe itching. Pubic lice can also infest the eyelashes, eyebrows, axilla, scalp, or other body hairs. Secondary bacterial infection can occur from excoriations, with ensuing regional lymphadenitis. Patients with *Phthirus pubis*should be evaluated for other sexually transmitted diseases.
- Scabies is caused by *Sarcoptes scabiei*. The female mite burrows under the skin to deposit eggs. The disorder is worldwide in distribution, and recently there have been increases in the number of cases in the United States and Europe. Scabies most commonly affects families, sexual partners, school-aged children, chronically ill patients, and people in communal living situations. Immunocompromised patients are prone to develop crusted or Norwegian scabies, which often leads to debilitating pain and skin breakdown. The mode of transmission of all forms is person-to-person contact or contact with clothing, towels, or linens. Epidemics within healthcare facilities have occurred in the United States.
- Syphilis is a complex systemic illness caused by the spirochete *Treponema pallidum*. Syphilis is acquired by sexual contact; passage through the placenta (congenital syphilis); kissing or other close contact with an active lesion; transfusion of human blood; or accidental direct inoculation. The rate of primary and secondary syphilis reported in the United States show that gay and bisexual men and young people are at the greatest risk. In 2011, men who have sex with men accounted for 72 percent of the primary and secondary syphilis cases in the United States. Clinically, syphilis is categorized as primary, secondary, early latent, late latent, latency of unknown duration, and tertiary. Patients may seek treatment for signs and symptoms of primary syphilis, such as a papule or chancre at the site of infection. Secondary syphilis demonstrates manifestations that include, but are not limited to, skin rash, patchy hair loss (alopecia areata), mucocutaneous lesions, and lymphadenopathy. Latent infections typically are those that lack clinical manifestations and are detected by serologic testing. Tertiary infection can encompass cardiac (aortic root aneurysm/aortic insufficiency), ophthalmic, and auditory sequelae; central nervous system complications (neurosyphilis); aseptic meningitis; generalized paresis; and tabes dorsalis. Gummatous lesions of the soft tissue and bone may be observed. Untreated, early syphilis in pregnant women results in perinatal death in as many as 40 percent of cases, and if acquired during the 4 years preceding pregnancy, may lead to infection of the fetus in more than 70 percent of cases. All patients with syphilis should be tested for human immunodeficiency syndrome.
- Three main clinical entities cause vaginitis: trichomoniasis, vulvovaginal candidiasis, and bacterial vaginosis. Trichomoniasis is sexually transmitted, whereas candidiasis usually is not. The role of sexual transmission is unknown in bacterial vaginosis. Vaginitis is characterized by a vaginal discharge or vulva itching and irritation; a fishy odor may be present.
- Lymphogranuloma venereum is caused by *C. trachomatis*serovars L1, L2, or L3. These strains are distinct from those that cause nongonococcal urethritis. Lymphogranuloma venereum is endemic in many parts of the world, including Asia, Africa, and South America. It is rare in the United States, where it is seen predominantly among homosexual males. Lymphogranuloma venereum is the only *C. trachomatis*infection that causes constitutional symptoms. In the first phase, a small, painless herpetiform vesicle, nonindurated papule, or ulcer may develop locally. This lesion may heal quickly and is followed by inguinal or perirectal lymphadenopathy or bubo, fever, and other constitutional symptoms. The third phase of illness is characterized by lymph node suppuration, abscess,

lymphedema, or fistula formation, or a combination of these. A presumptive diagnosis is made by excluding other causes of genital ulcers or inguinal lymphadenopathy and is supported by the detection of *C. trachomatis.*

- Hysterectomies are the second most common surgical procedure for women of reproductive age (behind cesarean section) in the United States. Posthysterectomy infections usually arise from contamination of the surgical site by endogenous flora. The length of hospital stay for all types of hysterectomies has decreased, and many patients are discharged before manifestation of a postoperative wound infection is recognized. Postdischarge surveillance is necessary to identify these infections. Perioperative antibiotic prophylaxis is recommended for hysterectomies to decrease the risk of postoperative wound infection.
- Procedures that do not result in operative site exposure to flora in the lower genital tract include laparoscopy, ovarian cystectomy, and hysterosalpingography; therefore, antibiotic prophylaxis is not recommended for these procedures.
- Pelvic gynecologic surgeries, like other pelvic procedures, pose an increased risk of occupational exposure of healthcare personnel to bloodborne pathogens.

Background

The Centers for Disease Control and Prevention (CDC) estimates that 20 million sexually transmitted diseases (STDs) occur annually in the United States, and almost half are among young people between the ages of 15 and 24 years.[1]Many STDs are undiagnosed; others are not reported, including common viral infections, such as human papillomavirus (HPV) and genital herpes. These diseases represent a significant public health threat.

Efforts to prevent, detect, and treat STDs have had some success. For example, new vaccines promise to decrease the morbidity and mortality associated with HPV and its complications. Several challenges, including increasing rates of several STDs and establishment of antimicrobial resistance, have emerged. In addition, disparities in STD prevalence by gender, socioeconomic class, race, and sexual orientation persist.

Basic Principles

Patients suffering from one STD may also have one or more other STDs. Patients and their sex partners should be screened and treated accordingly. The presence of STDs increases the likelihood of both transmitting and acquiring human immunodeficiency virus (HIV). Individuals with STDs are three to five times more likely to acquire HIV if exposed to the virus through sexual contact than are noninfected individuals. Conversely, if an HIV-infected individual is coinfected with an STD, he or she is three to five times more likely than other HIV-infected persons to transmit HIV through sexual contact. The lower part of the reproductive tract is heavily colonized with bacteria. Anaerobes are 10 times more common in the vagina than aerobes. Normal vaginal flora includes lactobacilli, various species of streptococci, *Gardnerella vaginalis*, strains of Enterobacteriaceae, and anaerobes. A number of naturally occurring events can alter the vaginal flora, including pregnancy, delivery, menopause, abdominal or vaginal hysterectomy, and hospitalization.

Either the vaginal or the abdominal routes are used to perform gynecologic procedures. The vaginal route is a clean, nonsterile approach, thereby increasing the risk of infection through contamination by

vaginal flora. The abdominal route is a sterile approach that carries postoperative wound infection risks similar to those for other abdominal clean surgical procedures.

Sexually Transmitted Diseases And Gynecology

SEXUALLY TRANSMITTED DISEASES

Chlamydia Infections

In the United States alone during 2011, 1,412,791 cases of genital *Chlamydia trachomatis*infections were reported to the CDC. This case count corresponds to a rate of 457.6 cases per 100,000 and represents an increase of 8 percent compared with the previous year. The increase most likely represents increased screening for chlamydia, more complete reporting, and more sensitive testing methods.[1]

Chlamydiae are obligate intracellular bacteria with a biphasic life cycle. The extracellular "elementary body" is the infectious form of the organism, whereas the "reticulate body" is the replicative form. The incubation period has not been clearly defined, but it is probably 7 to 14 days or longer.[2]Genital infection with *C. trachomatis*may result in urethritis, epididymitis, cervicitis, acute salpingitis, or other pelvic symptoms. Patients may present with dysuria and urethral discharge. The discharge tends to be gray, white, and sometimes clear, and may be either slight or copious in amount. However, the infection is often asymptomatic in men and women. Perinatal infections may result in inclusion conjunctivitis and pneumonia in newborns. The *C. trachomatis*infection may result in premature rupture of membranes, premature birth, and stillbirth. *C. trachomatis*is also the etiologic agent of lymphogranuloma venereum and trachoma.[3]

The most serious sequelae of *C. trachomatis*in women include pelvic inflammatory disease (PID), ectopic pregnancy, and infertility.[4]In men, sequelae include epididymitis, prostatitis, proctitis, proctocolitis, and Reiter syndrome.[5]

The CDC recommends that sexually active women <25 years of age should be screened at least annually, even if symptoms are not present. Screening of older women with risk factors (i.e., those with new or multiple sex partners) is also recommended. Sexually active men in high-prevalence settings such as STD clinics and correctional facilities should also be tested.[4]However, the United States Preventive Services Task Force (USPTF) recommends screening for persons less than 24 years of age.[6]

Classic trachoma is the only *C. trachomatis*infection that can be diagnosed on clinical grounds alone in the proper epidemiologic setting. Trachoma is an eye infection that is not sexually transmitted. Other chlamydial infections require laboratory confirmation for a definitive diagnosis. In females, *C. trachomatis*infection can be diagnosed by testing urine or endocervical or vaginal specimen swabs. In males, a specimen obtained from urine or urethral swab can be used. Rectal infection can be diagnosed from a rectal swab specimen. Nucleic acid amplification tests (NAATs) are the most sensitive tests for detecting chlamydiae and are approved by the United States. Culture, direct immunofluorescence, demonstration of chlamydial antigen by enzyme-linked immunosorbent assay (ELISA), and nucleic acid hybridization tests are also used.[2]Self-collected vaginal swabs perform as well as those collected by providers and are an acceptable specimen collection method by women.[4]

An average of five or more polymorphonuclear leukocytes per oil immersion field in a Gram stain from an endourethral swab or the presence of 10 leukocytes per high-power field in first-catch urine strongly suggests urethritis. The absence of organisms suggesting *N. gonorrhoeae* establishes the diagnosis of nongonococcal urethritis (NGU) in the proper clinical setting. In men, *C. trachomatis* has become slightly less prevalent but still accounts for 15 to 55 percent of NGU infections. The etiology of the majority of cases of nonchlamydial NGU is unknown. Possible etiologic agents of NGU include *Mycoplasma genitalium*, *Ureaplasma urealyticum*, herpes simplex virus (HSV), adenovirus, and *Trichomonas vaginalis*.[2] Enteric bacteria have been identified as an uncommon cause of NGU and may be associated with insertive anal sex. Diagnostic and treatment procedures for these organisms should be done only when these infections are suspected (e.g., contact with trichomoniasis and genital lesions or severe dysuria and meatitis, which may suggest genital herpes) or when NGU is not responsive to therapy. Although *C. trachomatis* and *N. gonorrhoeae* may be implicated as etiologic agents of mucopurulent cervicitis (MPC), in most cases the organisms cannot be isolated.[3] Mucopurulent cervicitis may be diagnosed if a purulent or mucopurulent endocervical exudate is seen or a friable endocervical mucosa is evident. Empiric treatment should be considered for a patient who is suspected of having gonorrhea or chlamydia if the prevalence of these infections is high in the patient population and if follow-up cannot be assured.[4]

The recommended treatment regimens for *C. trachomatis* infection include azithromycin (1 g by mouth [PO] in a single dose) or doxycycline (100 mg PO twice daily [bid] for 7 days). Alternative regimens include erythromycin base (500 mg PO bid for 7 days); erythromycin ethylsuccinate (800 mg bid for 7 days); ofloxacin (300 mg PO bid for 7 days); or levofloxacin (500 mg daily for 7 days). HIV-infected patients should receive the same treatment as those not infected with HIV. In cervicitis, consideration for treating *Neisseria gonorrhoeae* should be entertained if the local prevalence of gonococcal infections is greater than 5 percent.[4]

Patients should be instructed to abstain from sexual intercourse for 7 days after the one-dose treatment of azithromycin or until completion of a 7-day regimen. In general, patients do not need to be retested after completing treatment with doxycycline or azithromycin unless symptoms persist, reinfection is suspected, or the patient is pregnant.[4]

Treating infected patients prevents transmission to sex partners. Treatment of sex partners helps prevent reinfection of the index patient and transmission to other partners. Patients should be instructed to refer their sex partners for evaluation, testing, and treatment if they had sexual contact with the patient during the 60 days preceding onset of the patient's symptoms or chlamydia diagnosis. The most recent sex partner should be evaluated and treated, even if the last sexual contact has been longer than 60 days since the onset of symptoms or diagnosis. If local medical laws and regulations permit and concerns exist that heterosexual sex partners who are referred for evaluation and treatment will not seek these services, patient delivery of antibiotic therapy through a prescription or the medication itself to their partners can be considered.[4]

Recommended regimens for the treatment of pregnant women are azithromycin (1 g in a single dose) or amoxicillin (500 mg bid for 7 days). Tetracyclines and fluoroquinolones are contraindicated in pregnancy. Unlike the general population, pregnant women should routinely have repeat testing for chlamydia by NAAT 3 weeks after the completion of treatment.[4]

Neonatal *C. trachomatis* infection results from perinatal exposure to the mother's infected cervix. Prenatal screening and treatment of pregnant women can prevent neonatal chlamydial infections. Neonatal ocular

prophylaxis with silver nitrate solution or antibiotic ointments does not prevent perinatal transmission of *C. trachomatis*from mother to infant, but it should be done because ocular prophylaxis with these agents prevents gonococcal ophthalmia. Chalmydia should be considered for all infants aged ≤30 days with conjunctivitis, especially if the mother has a history of untreated chlamydia infection. However, neonatal *C. trachomatis*infection is most frequently recognized by conjunctivitis that develops 5 to 12 days after birth. *C. trachomatis*also can cause a subacute, afebrile pneumonia with onset at ages 1 to 3 months. Although *C. trachomatis*has been the most frequent identifiable infectious cause of ophthalmia neonatorum, perinatal chlamydial infections (including ophthalmia and pneumonia) have occurred less frequently because of the institution of widespread prenatal screening and treatment of pregnant women.[4]

Opthalmia neonatorum in the neonate can be diagnosed using both tissue culture and nonculture tests (e.g., direct fluorescence antibody [DFA] tests, enzyme immunoassay, and NAAT). Most nonculture tests are not cleared by the FDA for the detection of chlamydia from conjunctival swabs, and clinical laboratories must verify the procedure according to Clinical Laboratory Improvement Amendments (CLIA) regulations. Specimens for culture isolation and nonculture tests should be obtained from the everted eyelid using a dacron-tipped swab or the swab specified by the manufacturer's test kit, and they must contain conjunctival cells, not exudate alone. Specific diagnosis of *C. trachomatis*infection confirms the need for treatment not only for the neonate but also for the mother and her sex partner(s). Ocular specimens from infants being evaluated for chlamydial conjunctivitis also should be tested for *N. gonorrhoeae*.[4]

The recommended treatment of neonatal *C. trachomatis*is erythromycin base or ethylsuccinate 50 mg/kg/day PO divided into four doses daily for 14 days. Because the efficacy of erythromycin treatment is only approximately 80 percent, a second course of therapy might be necessary. Note that an association between oral erythromycin and infantile hypertrophic pyloric stenosis (IHPS) has been reported in infants aged <6 weeks who were treated with this drug. Infants treated with erythromycin should be followed for signs and symptoms of IHPS. Topical antibiotic therapy alone is inadequate for treatment of chlamydial infection and is unnecessary when systemic treatment is administered. Infant follow-up is recommended to determine whether initial treatment was effective.[4]

The possibility of concomitant chlamydial pneumonia should be considered. The characteristic signs of chlamydial pneumonia in infants include (1) a repetitive staccato cough with tachypnea and (2) hyperinflation and bilateral diffuse infiltrates on a chest radiograph. In addition, peripheral eosinophilia (≥400 cells/mm^3) occurs frequently. Wheezing is rare, and infants are typically afebrile. Because clinical presentations differ, initial treatment and diagnostic tests should include *C. trachomatis*for all infants aged 1 to 3 months who are suspected of having pneumonia (especially those whose mothers have untreated chlamydial infection). The recommended treatment is erythromycin base or ethylsuccinate PO divided into four doses daily for 14 days. Because the efficacy of erythromycin treatment is only approximately 80 percent, a second course of therapy might be necessary. Infant follow-up is recommended to determine if the pneumonia has resolved, though some infants with chlamydial pneumonia continue to have abnormal pulmonary function tests later in childhood.[4]

The recommended infection prevention measures include Standard Precautions.[7]

Neisseria gonorrhoeae Infection

Gonorrhea is the second most common notifiable disease reported in the United States.[8] Following a 73.8 percent decline in the reported rate of gonorrhea from 1975 to 1997, overall rates increased 4 percent between 2010 and 2011 to 104.2 per 100,000 population, or 321,849 reported cases, in 2011. The prevalence of *N. gonorrhoeae* infection varies widely by geographical region. *N. gonorrhoeae* infection also highlights some striking disparities among race; the gonorrhea rate among blacks was 17 times that of whites in 2011. The gonorrhea rate of African-American women is 14 times that of white women. As with chlamydia, rates of gonorrhea in women are particularly high in the 15-to-24-year-old group. In men, rates are highest in the 20-to-29-year-old group.[1]

N. gonorrhoeae is a nonmotile, nonspore forming, Gram-negative diplococcus that can be observed within neutrophils during microscopic examination of a Gram-stained specimen. Aside from perinatal transmission, the dominant risk factor for acquiring gonorrhea is sexual intercourse with an infected partner. Transmission by fomites (including linens and towels) has been a rare cause of epidemic spread of gonococcal vaginitis.[4]

The incubation period is generally 2 to 5 days but ranges from 1 to 10 days or longer. More than 90 percent of men have no symptoms with urethritis as the predominant manifestation. Urethral discharge and dysuria are the major symptoms. As opposed to NGU, the discharge generally is more profuse and purulent. In women, the primary locus of disease is the endocervix. As with *C. trachomatis*, many women have no or only minor symptoms. The predominant symptoms are those of cervicitis, occasional urethritis, increased vaginal discharge, and intermenstrual bleeding. Abdominal or pelvic pain is suggestive of salpingitis.[9] Anorectal and pharyngeal infections are common. Approximately 40 percent of women with gonococcal cervicitis have positive rectal cultures and 20 percent display symptoms of gonococcal pharyngitis.[6]

Because the prevalence of gonorrhea is variable, healthcare providers should consider local gonorrhea epidemiology when making screening decisions. Widespread screening is not recommended because gonococcal infections among women are frequently asymptomatic; targeted screening of young women (i.e., those aged <25 years) at increased risk for infection is a primary component of gonorrhea control in the United States. The U.S. Preventive Services Task Force (USPSTF) does not recommend screening for gonorrhea in men and women who are at low risk for infection. The USPSTF recommends screening sexually active women, including those who are pregnant. Clinicians should also provide gonorrhea screening to patients at increased risk for infection, such as women with previous gonorrhea infection, other STDs, and those with new or multiple sex partners especially if there is a history of inconsistent condom use. Also included are those who use drugs illegally or engage in commercial sex work, and those living in communities with a high prevalence of disease. All persons found to have gonorrhea also should be tested for other STDs, including chlamydia, syphilis, and HIV.[4]

For men with symptoms, a Gram stain of a male urethral specimen that demonstrates polymorphonuclear leukocytes with intracellular Gram-negative diplococci can be considered diagnostic because of high specificity (>99 percent) and sensitivity (>95 percent). However, because of lower sensitivity, a negative Gram stain should not be considered sufficient to rule out infection in men who have no symptoms. Gram stain of endocervical specimens, pharyngeal, or rectal specimens also is insufficient to detect infection and thus is not recommended. With the increased utility and availability of highly sensitive and specific testing methods, and because a specific diagnosis may enhance partner notification, specific laboratory testing for *N. gonorrhoeae* is recommended.[4]

Laboratory diagnosis of gonorrhea relies on the identification of *N. gonorrhoeae* at the infected site. Culture, nucleic acid hybridization, or NAATs can be used for the diagnosis of genital infection. NAATs offer the widest range of testing specimen types because they are FDA cleared for use with endocervical swabs, vaginal swabs, male urethral swabs, and female and male urine. However, product inserts for each NAAT vendor must be carefully examined to assess current indications because FDA-cleared specimen types may vary. NAATs are highly sensitive and specific. DNA amplification by either polymerase chain reaction (PCR) or ligase chain reaction offers sensitivity and specificity comparable, or even superior, to culture. The convenience of these latter tests makes screening much more practical. In nongenital sites (i.e., rectum and pharynx), the culture should be used. Some NAATs may cross-react with nongonococcal *Neisseria* and related organisms that are commonly found in the throat. Note that some noncommercial laboratories have initiated the NAAT of rectal and pharyngeal swab specimens after establishing the performance of the test to meet the CLIA requirements.[4]

Because nonculture tests cannot provide antimicrobial susceptibility results, in cases of persistent gonococcal infection after treatment, clinicians should perform both culture and antimicrobial susceptibility testing. For legal purposes, a confirmed culture is the only definitive test.[9] When obtaining a culture is not practical or possible, a presumptive diagnosis can be based on microscopic identification of Gram-negative intracellular diplococci on a smear of urethral or endocervical exudates.[5] All patients tested for gonorrhea should also be tested for other STDs, including Chlamydia, syphilis, and HIV.[4]

Until recently, treatment was empiric and susceptibility testing was not routinely done. The CDC started a surveillance system to monitor resistant strains of *N. gonorrhoeae* in 1986. The Gonococcal Isolate Surveillance System (GISP) is a CDC-supported sentinel surveillance system to monitor *N. gonorrhoeae* susceptibility among urethral isolates obtained from men at participating STD clinics. Data from GISP are used to develop treatment recommendations before widespread treatment failures can adversely impact individual patients and become a major public health problem. Effective treatment of *N. gonorrhoeae* remains the central component of prevention and control of this organism.[10]

When discussing treatment options, several principles must be considered. Patients infected with *N. gonorrhoeae* are often coinfected with *C. trachomatis*. This has led to the recommendation that patients treated for gonococcal infections also receive treatment with a regimen effective against uncomplicated *C. trachomatis* infection. This can be cost effective, and some specialists believe the practice has resulted in substantial decreases in the prevalence of chlamydial infections.[4]

Using GISP, the CDC tracked the emergence of fluoroquinolone-resistant *N. gonorrhoeae* (QRNG) in the United States. QRNG initially emerged in Asia during the early 1990s. It was sporadically seen in the United States until the early 2000s when it initially emerged in Hawaii and California. Men who have sex with men (MSM) were disproportionately infected. By 2007, the prevalence of QRNG in the United States exceeded 5 percent of GISP isolates. The cephalosporins remained the treatment of choice for *N. gonorrhoeae* in the 2010 CDC STD treatment guidelines.[10]

Cephalosporin resistance was initially noted in Asia during the 2000s and later in Europe. Through GISP, the CDC documented cephalosporin resistance in the United States, specifically an increase in the minimum inhibitory concentrations (MIC) of cefixime. The increases were most pronounced in isolates from MSM in the same regions where QRNG emerged in the United States.[10]

Treatment of *N. gonorrhoeae*is complicated by cephalosporin resistance, and particularly by resistance to ceftriaxone. Because previously recommended treatment regimens may no longer be effective, the CDC published a major change in its treatment guidelines on February 15, 2013. The preferred regimen is ceftriaxone (IM) for one dose plus azithromycin PO for one dose or doxycycline for 7 days. The alternative regimen for urogenital or rectal *N. gonorrhoeae*is as follows: (1) if ceftriaxone is not available, cefixime PO for one dose plus azithromycin PO for one dose or doxycycline PO bid for 7 days; (2) if the patient has a severe cephalosporin allergy, azithromycin PO for one dose. Laboratories that detect cephalosporin isolates with an MIC >0.25 µg/mL for cefixime or an MIC >0.125 µg/mL for ceftriaxone should promptly notify the ordering clinician and the local STD control program.[10]

Patients with gonococcal infection who are coinfected with HIV should receive the same treatment regimen as those who do not have HIV.[4]

For pharyngeal gonorrhea, the CDC recommends a single intramuscular dose of ceftriaxone plus azithromycin PO for one dose or doxycycline PO daily for 7 days.[4]

In the pregnant patient, the use of a cephalosporin-based regimen is recommended. Because spectinomycin is no longer available in the United States, azithromycin PO can be considered for women who cannot tolerate a cephalosporin. Either azithromycin or amoxicillin is recommended for treatment of presumptive or diagnosed *C. trachomatis*infection during pregnancy.[4]

In patients with gonococcal conjunctivitis, a single dose of ceftriaxone is recommended. A one-time saline lavage of the infected eye should be considered. Patients treated for gonococcal conjunctivitis should also be treated presumptively for concurrent *C. trachomatis*infection.[4]

In patients with evidence of disseminated gonococcal infections, petechial or pustular acral lesions, asymmetrical arthralgia, tenosynovitis, or septic arthritis, the recommended regimen is ceftriaxone (1 g intravenous [IV] daily). Alternative regimens include cefotaxime and ceftizoxime. If unable to use cephalosporins, spectinomycin would be acceptable. All of the preceding regimens should be continued for 24 to 48 hours after improvement is observed, at which time the patient may be switched to cefixime to complete a full 7 days of antibiotic therapy. In patients with gonococcal endocarditis, treatment with ceftriaxone (IV every 12 hours for at least 4 weeks) is recommended, and in patients with meningitis, treatment for 10 to 14 days is advised.[4]

Infected mothers may transmit *N. gonorrhoeae*to the newborn in utero, perinatally, or in the postpartum period. Gonococcal conjunctivitis of the newborn (ophthalmia neonatorum) is the most commonly recognized manifestation. The most important preventative measure is routine screening and treatment of pregnant women for gonorrhea before delivery. Ocular prophylaxis using erythromycin opthalmic ointment 0.5 percent in each eye is recommended for all neonates because it can prevent sight-threatening gonococcal ophthalmia and because it is safe, easy to administer, and inexpensive. Erythromycin is the only antibiotic ointment currently recommended for use in neonates. Although used in the past, silver nitrate and tetracycline ophthalmic ointment are no longer available in the United States. Bacitracin is not effective and povidone iodine has not been studied adequately. If erythromycin ointment is not available, infants at risk for exposure to *N. gonorrhoeae*(especially those born to a mother with untreated gonococcal infection or who have received no prenatal care) can be administered ceftriaxone. Nongonococcal causes of neonatal ophthalmia include *Moraxella catarrhalis*, and other *Neisseria*species that are indistinguishable from *N. gonorrhoeae*on a Gram stain. The treatment of

choice is ceftriaxone. Topical antibiotic treatment alone is not adequate to treat established infections and is unnecessary if systemic treatment is instituted.[4]

Patients with uncomplicated *N. gonorrhoeae* who are treated with one of the recommended or alternative regimens do not need to routinely return for a test or cure. Patients with symptoms that persist after treatment or whose symptoms recur shortly after treatment with a recommended or alternative regimen should have a culture for *N. gonorrhoeae*, and any gonococci that are isolated should be tested for antimicrobial susceptibility. The clinicians and laboratories should report treatment failures or resistant gonococcal isolates to the CDC through the state and local public health authorities.[8]

Because the majority of infections identified after treatment with one of the recommended regimens result from reinfection, rather than treatment failure, clinicians should consider advising all patients with *N. gonorrhoeae* to be retested 3 months after treatment. If patients do not return for retesting in 3 months, providers are encouraged to test these patients whenever they next seek medical care within the following 12 months, regardless of whether the patient believes his or her sex partners were treated. Retesting is different from test of cure to detect therapeutic failure, which is not recommended.[4]

There is a need for patient education and referral and treatment of sex partners. Persistent urethritis, cervicitis, or proctitis may be caused by *C. trachomatis* and other organisms.[4]

All sex partners of a patient with diagnosed *N. gonorrhoeae* or *C. trachomatis* should be evaluated and treated if their last sexual encounter was within 60 days before the onset of symptoms or diagnosis of the index patient. If a patient's last sexual intercourse was more than 60 days before diagnosis or the onset of symptoms, the patient's most recent sex partner should be treated. Expedited partner therapy is a potential mechanism for treating heterosexual partners of patients infected with *N. gonorrhoeae* in certain jurisdictions.[5] If this strategy is employed, educational materials should also be provided to the partner in addition to a prescription or the actual antimicrobial. Partner-delivered therapy currently is not recommended for homosexual males. The patients and their sex partners should be instructed to avoid sexual intercourse until the therapy is completed and they no longer have symptoms.[4]

The recommended infection prevention measures include Standard Precautions.[7]

Genital and Anal Warts (Condyloma Acuminatum): Human Papillomavirus

Human papillomavirus (HPV) is the most common sexually transmitted viral disease in the United States.[11] It is estimated that more than 50 percent of sexually active persons become infected at least once in their lifetime. More than 100 types of HPV exist, of which, more than 40 types can infect the genital area. The majority of HPV infections are asymptomatic, unrecognized, or subclinical. HPV usually is self-limited and occurs more frequently than visible genital warts among both men and women and cervical cell changes among women.[5] A recently developed vaccine should decrease the sequelae of infection with HPV.[4]

Certain types of HPV (e.g., types 6 and 11) cause genital and anal warts. Other HPV types in the anogenital region (e.g., types 16, 18, 31, 33, and 35) have been strongly associated with cervical tumors.[4]

Typical genital warts are single or multiple soft, fleshy, papillary or sessile, painless growths around the anus, vulva-vaginal area, penis, urethra, or perineum. Most HPV infections are asymptomatic, subclinical, or unrecognized.[4]In circumcised men, the penile shaft is the most common site of lesions, and the preputial cavity is involved in 85 to 90 percent of the cases. Most lesions in women are found over the posterior introitus and, less frequently, on the labia and the clitoris, as well as the perineum, vagina, anus, cervix, and urethra.[9]In addition, to the external genitalia (i.e., penis, vulva, scrotum, perineum, and perianal skin), genital warts can occur on the uterine cervix and in the vagina, urethra, anus, and mouth. Intra-anal warts are observed predominantly in patients who have had receptive anal intercourse. These warts are distinct from perianal warts, which can occur in men and women who do not have a history of anal sex. HPV types 6 and 11 have also been associated with conjunctival, nasal, oral, and laryngeal warts. Genital warts are usually asymptomatic, but depending on the size and anatomic location, genital warts can be painful, friable, or pruritic.[4]

Complications and sequelae of HPV infection include tissue destruction from enlarging lesions. During pregnancy, the warts are extremely vascular and can enlarge and possibly cause obstruction of the birth canal, necessitating cesarean section. Malignant transformation of anal condylomata may occur.[11]

A presumptive diagnosis is based on clinical appearance. Condyloma latum (secondary syphilis) can be excluded by obtaining dark-field examination or serologic tests for syphilis or both. Some providers with experience and expertise treating genital warts find it useful to apply 3 to 5 percent acetic acid. This usually turns HPV-infected genital mucosal tissue to a whitish color. Acetic acid application is not a specific test for HPV infection, and the specificity and sensitivity of this procedure for screening have not been defined. Therefore, the routine use of this procedure for screening to detect HPV infection is not recommended.[4]

HPV tests that detect viral nucleic acid (i.e., DNA or RNA) or capsid protein are available for women over 30 years of age undergoing cervical cancer screening. The four tests approved by the FDA for use in the United States are the HC II High-Risk HPV test (Qiagen), HC II Low-Risk HPV test (Qiagen), Cervista HPV 16/18 test, and Cervista HPV High-Risk test (Hologics). These tests should not be used for men, for women under 20 years of age, or as a general test for STDs.[4]The use of HPV DNA testing should supplement, not replace, Pap testing.[12]

Women with HPV infection on such testing should be counseled that HPV infection is common, infection is frequently transmitted between partners, and that infection usually goes away on its own. If any Pap test or biopsy abnormalities have been observed, further evaluation is recommended. Screening women or men with the HPV test, outside of the above recommendations for use of the test with cervical cancer screening, is not recommended.[4]

Vaginal or cervical warts are often found only by culdoscopy or Pap test. Subclinical infection often is diagnosed indirectly on the cervix by Pap test, colposcopy, or biopsy results, and on the penis, vulva, and other genital skin by the appearance of white areas after application of acetic acid. Histologic changes suggestive of HPV infection can be demonstrated with Pap smear testing.[4]

The diagnosis can be confirmed by biopsy, but this is rarely needed. A biopsy should be obtained if the diagnosis is uncertain; the lesions do not respond to standard therapy; the disease worsens during

standard therapy; the patient is immunocompromised; or the warts are pigmented, indurated, fixed, or ulcerated.[4]

The primary goal of treatment is to remove visible warts. Treatment can result in wart-free periods for many patients. The treatment selected is based on patient preference, available resources, and provider experience. There is no ideal treatment for all patients and no evidence to suggest that any one treatment is superior to the others. Treatment does not completely eliminate the risk of transmission but can lessen it. Untreated warts may remain unchanged, resolve spontaneously, or increase in size or number.[4]

The recommended treatments for external genital warts are either patient-applied or provider-administered. For patient-applied treatments, the patient must be able to identify and reach the warts to be treated. Recommended patient-applied treatments include podofilox (0.5 percent solution or gel bid for 3 days followed by 4 days of no therapy if the total wart area does not exceed 10 cm^2 and the total volume of podofilox is limited to 0.5 mL/day [treatment may be repeated for a total of four cycles; safety during pregnancy has not been established]); or imiquimod (5 percent cream at bedtime 3 times a week for as long as 16 weeks [safety during pregnancy has not been established]). The recommended provider-administered regimens include cryotherapy with liquid nitrogen or cryoprobe (application can be repeated every 1 to 2 weeks) or podophyllin (10 to 25 percent in a compound tincture of benzoin, repeated weekly if necessary if the total wart area does not exceed 10 cm^2 and the total volume of podophyllin is limited to 0.5 mL/day [safety during pregnancy has not been established]); trichloroacetic acid (TCA) or bichloracetic acid (BCA) (80 to 90 percent); or surgical removal via tangential scissor excision, tangential shave excision, curettage, or electrosurgery. Alternative treatments for external genital warts include intralesional interferon or laser surgery. For women with cervical warts, high-grade squamous intraepithelial lesions must be ruled out by colposcopy and a biopsy before treatment. A specialist with expertise in squamous intraepithelial lesions should provide care for these patients.[4]

Options for the treatment of vaginal warts include cryotherapy with liquid nitrogen (the use of a cryoprobe is not recommended in the vagina because of the risk of vaginal perforation or fistula formation), or TCA or BCA (80 to 90 percent) applied to the warts (can be repeated weekly).[4]

The recommended treatment for accessible meatal warts is cryotherapy with liquid nitrogen or podophyllin (10 to 25 percent in compound tincture of benzoin), which can be repeated weekly if necessary (safety during pregnancy has not been established). Although data are limited, some specialists also recommend using podofilox and imiquimod to treat distal meatal warts. Anal warts that are accessible by anoscope may be treated with cryotherapy with liquid nitrogen or with TCA or BCA (80 to 90 percent), which can be repeated weekly if necessary, or by surgical removal. Patients with warts on the rectal mucosa should be provided care in consultation with a specialist.[4]

Immunocompromised or HIV-infected patients may not have good response to HPV therapy and may experience more frequent recurrences. Squamous cell carcinomas occur more frequently among immunosuppressed persons and may arise in or resemble genital warts; therefore, a biopsy is recommended to confirm the diagnosis.[4]

The treatment of genital warts in pregnant women needs to take into consideration the potential adverse effects of some of the medications on the fetus, the risk of perinatal transmission, and potential mechanical obstruction of the vagina. The treatment options for pregnant women are more limited than

for other patients. Imiquimod, podophyllin, and podofilox should not be used during pregnancy. Because genital warts can proliferate and become friable during pregnancy, many specialists advocate their removal during pregnancy. HPV types 6 and 11 have been documented to cause respiratory papillomatosis in infants and children via an incompletely understood mechanism. The value of a cesarean section in preventing respiratory papillomatosis is unknown; thus, a cesarean section should not be performed solely to prevent transmission of HPV infection to the newborn. However, a cesarean section may be indicated for women with genital warts if the wart(s) obstruct the pelvic outlet or if vaginal delivery would result in excessive bleeding.[4]

Posttreatment follow-up after visible genital warts have cleared is not mandatory but may be helpful. Patients should be advised to watch for recurrences, which occur most frequently during the first 3 months. Because the sensitivity and specificity of self-diagnosis of genital warts are unknown, patients concerned about recurrences should be offered a follow-up evaluation 3 months after treatment. Earlier follow-up visits also may be useful for some patients to document the absence of warts, monitor for or treat complications of therapy, and provide an additional opportunity for patient education and counseling. Women should be counseled to undergo regular Pap screening as recommended for women without genital warts. The presence of genital warts is not an indication for a change in the frequency of Pap tests or for cervical colposcopy.[4]

Two HPV vaccines are licensed in the United States. Cervarix is a bivalent vaccine containing HPV types 16 and 18. Gardasil is a quadrivalent vaccine that includes HPV types 6, 11, 16, and 18. Both vaccines offer protection against the HPV types that cause 70 percent of cervical cancers (i.e., types 16 and 18). Gardasil also protects against the types that cause 90 percent of genital warts (i.e., types 6 and 11). Either vaccine can be administered to girls aged 11 to 12 years and can be administered to those as young as 9 years of age. Girls and women aged 13 to 26 years who have not started or completed the vaccine series also should receive the vaccine. HPV vaccine is indicated for girls in this age group because benefit is greatest if it is administered before the onset of sexual activity. Gardasil can also be used in males aged 9 to 26 years to prevent genital warts. Administering the vaccine to boys before the onset of sexual activity is optimal. Both HPV vaccines are administered as a three-dose series of IM injections over a 6-month period with the second and third doses given 1 to 2 and then 6 months after the first dose. Ideally, the same vaccine product should be used for the entire three-dose series.[4]HPV vaccination is not recommended for pregnant women but can be safely administered to breastfeeding mothers. Because it contains no infectious particles, the vaccine is safe in immunocompromised persons.[12]HPV vaccination is available for eligible children and adolescents under 19 years of age through the Vaccines for Children (VFC) program (available by calling CDC INFO [800-232-4636]). Women who received an HPV vaccine should continue routine cervical cancer screening because 30 percent of cervical cancers are caused by HPV types other than 16 or 18.[4]

A positive HPV DNA test result might cause partner concerns, worry about disclosure, and feelings of guilt, anger, and stigmatization. Counseling patients is important. Resources available to patients include pamphlets, hotlines (such as the CDC National STD/HIV Hotline 800-227-8922), and websites.[5](See Supplemental Resources.) The information should be provided in a neutral, nonstigmatizing context and emphasize that HPV is common, asymptomatic, and transient. Specific counseling messages should include the following:

- Genital HPV infection is caused by a virus that is common among sexually active adults.[4]

- Infection is usually sexually transmitted. Because the incubation period is variable, it is often difficult to determine the source of infection.[4]
- Within ongoing relationships, the sexual partner is usually infected by the time a patient is diagnosed, though there may be no symptoms or signs of infection.
- Because genital HPV is common among persons who have been sexually active, and because the duration of infectivity is unknown, the value of disclosing a past diagnosis of genital HPV infection to future partners is unclear.
- Candid discussions about other STDs should be encouraged and attempted whenever possible.
- The likelihood of transmission to future partners and the duration of infectivity after treatment are unknown. The use of latex condoms has been associated with a lower rate of cervical cancer, an HPV-associated disease.[4]
- The types of HPV that usually cause external genital warts are not associated with cancer.[4]
- Recurrence of genital warts within the first several months after treatment is common and usually indicates recurrence rather than reinfection.[4]

Women with high-risk HPV infections should be counseled about partner notification and provided with information that is individualized based on the patient's circumstances. Some women might benefit from having their partners included in an informed discussion about their diagnosis. Although there is no evidence that supports partner notification or partner clinical evaluation, referral for partners of patients with high-risk HPV might be appropriate and can include the following information:

- The immune system clears HPV infection most of the time.[4]
- In some persons, HPV infection does not resolve.[4]
- HPV is very common and usually has no symptoms.[4]
- It can infect the genital areas of both men and women.[4]
- Most sexually active persons get HPV at some time in their lives, though most will never know it.[4]
- Even persons with only one lifetime sex partner can get HPV if their partner was infected.[4]
- The most common manifestation of HPV infection in men is genital warts.[4]
- Partners who are in a long-term relationship tend to share HPV. Sexual partners of HPV-infected patients also likely have HPV, though they might have no signs or symptoms of infection.[4]
- Detection of high-risk HPV infection in a woman does not mean that the woman or her partner is engaging in sexual activity outside of a relationship.[4]

Prevention measures for current and subsequent sex partners and risk reduction should also be discussed. This includes counseling women about condom use if appropriate depending on their current circumstances. Consistent male condom use by partners of sexually active women can reduce the risk for cervical and vulvovaginal HPV infection. Condom use by couples in long-term partnerships may decrease the time required to clear the woman's HPV infection. Skin not covered by a condom remains vulnerable to HPV infection. HPV vaccines are available and recommended for girls and young women

aged 9 to 26 years, even in those who have been diagnosed with HPV infection. Male partners can be vaccinated with Gardasil to prevent genital warts.[4]

Routine screening and treatment of sex partners is not indicated. However, partners may benefit from recommending assessment for genital warts and other STDs and from counseling about HIV infection. The female sexual partners of a person with genital warts should be reminded that cytological screening for cervical cancer is recommended for all sexually active women.[4]

The recommended infection prevention measures include Standard Precautions.[7]

Herpes Genitalis

Genital herpes or herpes simplex is a chronic, lifelong viral infection caused by *Herpesvirus hominis*. This virus, known as HSV, is a DNA virus for which humans appear to be the only natural reservoir. Two types of HSV have been identified: HSV-1 and HSV-2. The majority of cases of recurrent genital herpes are caused by HSV-2, though HSV-1 may become more common as a cause of first-episode genital herpes. At least 50 million people in the United States have genital HSV infection.[4,13]The increase in the number of office visits for genital HSV suggests a growing incidence of genital herpes.[1]The principal mode of transmission is direct mucous membrane contact with infected secretions. (HSV-1 is transmitted primarily by contact with oral secretions and HSV-2 by contact with genital secretions.) Persons unaware that they have the infection or who have no symptoms when transmission occurs transmit the majority of genital herpes infections. The majority of people infected with HSV-2 have not had a diagnosis of genital herpes. Many such persons have mild or unrecognized infections but shed virus intermittently in the genital tract.[4,13]Counseling regarding the natural history of genital herpes, sexual and perinatal transmission, and methods to reduce transmission is integral to clinical management.[4]

The incubation period is 2 to 12 days.[11]Single or multiple vesicles appear anywhere on the genitalia. Typically, patients have bilateral lesions of the external genitalia. Vesicles may appear on an erythematous base and spontaneously rupture to form shallow ulcers. The lesions resolve spontaneously without scarring. The first occurrence is termed "primary infection." Primary infection has a mean duration of 12 days and may be associated with fever, malaise, anorexia, and tender bilateral inguinal adenopathy. Lesions of primary genital herpes can persist for several weeks in some patients. Approximately two-thirds of patients have subsequent, usually milder, recurrences. Recurrent infection is often preceded by prodromal symptoms such as pain, burning, tingling, or itching; the mean duration of recurrence is 4 to 5 days. The 1-year recurrence rate for the first episode of HSV-2 is 90 percent, whereas that for HSV-1 is 55 percent.[13]

Complications and sequelae of genital herpes can be due to local extension or spread beyond the genital region. Neuralgia, meningitis, ascending myelitis, urethral stricture, urinary retention, and secondary bacterial infection can occur. In neonates, virus from an active genital infection may be transmitted during vaginal delivery, causing neonatal herpes infection. Neonatal herpes infection can range from a mild localized infection to a fatal disseminated infection.[13]The evaluation of all patients who have genital ulcers should include serologic testing for syphilis and a diagnostic evaluation for HSV. *Haemophilus ducreyi*should be searched for in areas with high prevalence of chancroid. The specific tests utilized in the evaluation of genital ulcers include dark-field microscopy or a direct immunofluorescence test for *Treponema pallidum*, culture or antigen tests for HSV, and *H.*

*ducreyi*culture. If the *T. pallidum*studies are initially negative, some experts would recommend three consecutive monthly serologic syphilis tests. All patients should be tested for HIV at the time of diagnosis because patients with genital ulcerations are at increased risk for HIV infection.[4]

The diagnosis of genital herpes should be confirmed by laboratory testing because the clinical diagnosis of genital herpes is both insensitive and nonspecific. The classic painful multiple vesicular or ulcerative lesions are absent in many infected persons. Therefore, the diagnosis of genital herpes should be confirmed by laboratory testing and also because both type-specific and nontype specific antibodies to HSV develop during the first several weeks after infection and persist indefinitely; virologic tests and type-specific antibody tests should be done. Both laboratory-based and point-of-care tests for HSV-2 antibodies are available from capillary blood or serum during a clinic visit. The sensitivities of these tests vary from 80 to 98 percent and the specificities are at least 96 percent. False-negative results might be more frequent at early stages of infection. False-positive results can occur, especially in patients with a low likelihood of HSV infection. Repeat or confirmatory testing may be indicated in some settings, especially if recent genital herpes infection is suspected. Immunoglobulin M (IgM) testing for HSV is not useful because the IgM tests are not type specific and might be positive during recurrent episodes of herpes.[4]

Cell culture and PCR is the preferred HSV test. PCR assays for HSV DNA are the preferred test, as it is more sensitive than viral culture. Viral culture has a low sensitivity, especially if the lesions are recurrent, and the sensitivity decreases rapidly as the lesions heal. PCR is the test of choice for detecting HSV in spinal fluid to diagnose central nervous system (CNS) HSV infection. Viral culture isolates should be typed to determine which type of HSV is causing the infection. It should be noted that because the virus sheds intermittently, not detecting HSV by culture or PCR does not indicate an absence of HSV infection. Cytologic detection of cellular changes of HSV infection should not be used because it is an insensitive and nonspecific method of diagnosis. This is true both for genital lesions (i.e., Tzanck preparation) and for cervical Pap smears.[4]

Type-specific HSV serologic assays might be useful in the following scenarios: (1) recurrent genital symptoms or atypical symptoms with negative HSV cultures; (2) a clinical diagnosis of genital herpes without laboratory confirmation; or (3) a partner with genital herpes. HSV serologic testing should be considered for persons presenting for an STD evaluation (especially for persons with multiple sex partners), persons with HIV infection, and MSM with behaviors or conditions that increase risk for HIV acquisition. Screening for HSV-1 and HSV-2 in the general population is not indicated. Because nearly all HSV-2 infections are sexually acquired, the presence of type-specific HSV-2 antibody implies anogenital infection. These patients should be given education and counseling appropriate for persons with genital herpes. The presence of HSV-1 antibody alone is more difficult to interpret. Most persons with HSV-1 antibody have oral HSV infection acquired during childhood, which might be asymptomatic. Lack of symptoms in an HSV-1 seropositive person does not differentiate between anogenital, orolabial, or cutaneous infection. However, persons infected with HSV-1 are at increased risk for acquiring HSV-2.[4]

Although there is no known cure for genital herpes, antiviral chemotherapy provides clinical benefits to the majority of patients with symptoms and is the mainstay of management. Systemic antiviral drugs partially control the symptoms and signs of herpes episodes when used to treat first clinical episodes and recurrent episodes or when used as a daily suppressive therapy. Three antiviral medications have been shown to provide clinical benefit for genital herpes: acyclovir, valacyclovir, and famciclovir. Topical therapy with antiviral drugs gives minimal clinical benefit and is not recommended.[4]

The treatment recommendations for primary infection begin with a careful history that should be obtained to establish that this is the patient's first episode of genital herpes. The recommended regimens include acyclovir (400 mg PO bid for 7 to 10 days); acyclovir (200 mg PO five times a day for 7 to 10 days); famciclovir (250 mg PO bid for 7 to 10 days); or valacyclovir (1 g PO bid for 7 to 10 days). Allergic and other adverse reactions to acyclovir, valacyclovir, and famciclovir are uncommon. Acyclovir desensitization has been described. If healing is incomplete after 10 days of treatment, therapy can be extended.[4]

Most patients with an asymptomatic first episode of genital HSV-2 infection will have recurrent episodes of genital lesions. Because many patients with mild or infrequent outbreaks may benefit from antiviral therapy, treatment options should be discussed with all patients. Episodic antiviral therapy can shorten the duration of lesions. Effective treatment for recurrent genital herpes requires that treatment start during the prodrome or within 1 day after the onset of lesions. The patient should be provided with a supply of medication or a prescription for the medication with instructions on how to start treatment at the first sign of prodrome or genital lesions. The recommended regimens for episodic recurrent infection include acyclovir; famciclovir; or valacyclovir.[4]

Continuous suppressive therapy should be discussed with all patients with HSV-2 infection because recurrence is very common. Suppressive therapy decreases the rate of recurrence and reduces, but does not eliminate, subclinical viral shedding. The recommended regimens for daily suppressive therapy use the same drugs as in the treatment of episodic recurrent infections. Valacyclovir may be less effective than other valacyclovir- or acyclovir-dosing regimens for patients who have 10 or more recurrent episodes per year.[4]

IV therapy should be provided for patients with severe disease or complications requiring hospitalization (e.g., disseminated infection, pneumonitis, hepatitis, or encephalitis). The recommended regimen is acyclovir (IV every 8 hours for 2 to 7 days or until clinical improvement is attained), followed by oral antiviral agents to complete a proscribed course of therapy. The dose of acyclovir may need to be adjusted for patients with renal impairment.[4]

HSV lesions are common among persons infected with HIV. The lesions may be painful, severe, and atypical. Episodic or suppressive therapy with oral agents is often beneficial. The recommended regimens for episodic infection include acyclovir; famciclovir; or valacyclovir. The recommended regimens for daily suppressive therapy include acyclovir; famciclovir; or valacyclovir. For severe cases, treatment may need to be initiated with perinatal acyclovir. If lesions persist or recur during treatment, HSV resistance should be suspected. A viral isolate should then be obtained for sensitivity testing, and the patient should be treated in consultation with a specialist. All acyclovir-resistant strains are resistant to valacyclovir, and most are resistant to famciclovir. Foscarnet is often effective for the treatment of acyclovir-resistant genital herpes. Topical cidofovir gel also may be effective. This preparation is not commercially available and must be compounded at a pharmacy.[4]

Counseling of infected patients and their sex partners is important to help patients cope with infection and to prevent sexual and perinatal transmission. Initial counseling is provided at the first visit. However, patients need to learn about the chronic aspects of genital herpes after the initial episode subsides. Patients can be referred to many resources, including the CDC National STD/HIV hotline.[4]Specific counseling messages should include the following components:

- The natural history of genital herpes infection should be explained with emphasis on the potential for recurrent episodes, asymptomatic viral shedding, and sexual transmission.[4]
- During the first episode, patients should be advised that effective suppressive and episodic treatments are available for preventing or shortening the duration of recurrent episodes.[4]
- Asymptomatic persons diagnosed with HSV-2 infection by type-specific serologic testing should receive the same counseling messages as persons with symptomatic infection. In addition, they should be taught about the clinical manifestations of genital herpes.[4]
- Patients should be advised to abstain from sexual contact with uninfected partners while lesions or prodromal symptoms are present.[4]
- Latex condoms used consistently and properly may offer some protection if the infected areas are covered and protected by the condom. Condoms have been effective in preventing male-to-female transmission.[4]
- All patients with HSV infection should be encouraged to tell their current sex partners that they have genital herpes and to inform future sex partners before starting a sexual relationship.[4]
- Patients need to be advised that transmission of HSV can also occur during the asymptomatic periods. Asymptomatic shedding is more common for HSV-2 than HSV-1. Viral shedding is most frequent during the first 12 months of infection with HSV-2.[4]
- The risk of HSV-2 sexual transmission can be decreased by the daily use of valacyclovir by the infected person.[4]
- Sex partners, even those with no symptoms, should be advised that they may be infected. They should be offered type-specific testing.[4]

The risk for neonatal infection should be explained to all patients, including men. Pregnant women and women of childbearing age who have genital herpes should inform their obstetrical providers and those who will care for their newborn infant. Pregnant women who are not infected with HSV-2 should be advised to avoid intercourse during the third trimester with men who have genital herpes. Similarly, pregnant women who are not infected with HSV-1 should be counseled to avoid genital exposure to HSV-1 during the third trimester (e.g., oral sex with a partner with oral herpes and vaginal intercourse with a partner with genital HSV-1 infection).[4]

Sexual partners with asymptomatic HSV-2, as diagnosed by type-specific testing, should also receive these counseling messages. They should also be taught about the clinical manifestations of genital herpes.[4]

Sex partners are likely to benefit from evaluation and counseling. Symptomatic sex partners should be evaluated and treated the same way as patients with genital lesions. Sex partners with no symptoms should be questioned about genital lesions, encouraged to recognize symptoms, and offered type-specific serologic testing for HSV infection.[4]

HIV-infected persons may have prolonged or severe episodes of genital, perianal, or oral herpes. These patients may have severe, painful, and atypical lesions. HSV shedding is increased in HIV-infected persons. Although antiretroviral therapy reduces the severity and frequency of symptomatic genital

herpes, frequent subclinical shedding still occurs. Clinical manifestations of genital herpes might worsen during immune reconstitution after initiation of antiretroviral therapy.[4]

Suppressive or episodic therapy with oral antiviral agents is effective in decreasing the clinical manifestations of HSV among HIV-positive persons. The extent to which suppressive antiviral therapy will decrease HSV transmission from this population is unknown. HSV type-specific serologies can be offered to HIV-positive persons during their initial evaluation if infection status is unknown, and suppressive antiviral therapy can be considered in those who have HSV-2 infection. The daily recommended suppressive therapy for HIV-infected persons is acyclovir, famciclovir, or valacyclovir. The recommended episodic therapy is acyclovir for 5 to 10 days, famciclovir for 5 to 10 days, or valacyclovir 5 to 10 days.[4]

If lesions persist or recur in an HIV-infected patient receiving antiviral treatment, HSV resistance should be suspected. A viral isolate should be obtained for sensitivity testing. These patients should be managed in consultation with an HIV specialist, and alternate therapy should be administered. All acyclovir-resistant strains are resistant to valacyclovir, and the majority are also resistant to famciclovir. Foscarnet, every 8 hours until clinical resolution is attained, is frequently effective to treat acyclovir-resistant genital herpes. Intravenous cidofovir once weekly might also be effective. Imiquimod is a topical alternative, as is topical cidofovir gel 1 percent, which is not commercially available and must be compounded at a pharmacy. These topical preparations should be applied to the lesions once daily for 5 consecutive days.[4]

Most babies who acquire neonatal herpes are born to mothers who lack histories of clinically evident genital herpes. The risk for perinatal transmission is high (30 to 50 percent) among women who acquire genital herpes near the time of delivery. The risk of perinatal transmission is low (≤1 percent) among women with histories of recurrent herpes at term or those who acquire genital HSV during the first half of pregnancy. Prevention of neonatal herpes depends on preventing acquisition of genital HSV infection during late pregnancy and avoiding exposure of the infant to herpetic lesions during delivery.[4]

Pregnant women in the third trimester without known genital herpes should be counseled to avoid intercourse with partners known or suspected of having genital herpes and to avoid cunnilingus with partners known or suspected to have orolabial herpes. Some specialists believe that type-specific serologic tests may be used to identify pregnant women at risk for HSV infection and to guide counseling with regard to the risk of acquiring genital herpes during pregnancy. Such testing and counseling may be especially important when a woman's sexual partner has HSV infection.[4]

All pregnant women should be asked whether they have a history of genital herpes. At the onset of labor, all women should be questioned carefully about symptoms of genital herpes, including prodrome, and should be examined carefully for herpetic lesions. Women without symptoms or signs of genital herpes or its prodrome can deliver vaginally. Most specialists recommend that women with recurrent genital herpetic lesions at the onset of labor should be delivered by cesarean section to prevent neonatal herpes. However, such delivery does not eliminate the risk for HSV transmission to the infant completely. Routine viral cultures of pregnant women with recurrent genital herpes are not recommended for those with or without visible herpetic lesions because they do not predict viral shedding at the time of delivery.[4]

The safety of systemic acyclovir, valacyclovir, and famciclovir therapy in pregnant women has not been established. Acyclovir may be administered orally to pregnant women with a first episode of genital herpes or severe recurrent herpes and should be administered intravenously to pregnant women with

severe HSV infection. Preliminary data suggest that acyclovir treatment late in pregnancy may reduce the frequency of cesarean sections among women who have recurrent genital herpes by diminishing the frequency of recurrences at term. Some specialists recommend this treatment. Because the risk for herpes is high for infants of women who acquire genital HSV in late pregnancy, these women should be treated in consultation with an HSV specialist. Some specialists recommend acyclovir therapy in this circumstance; some recommend routine cesarean section to reduce the risk for neonatal herpes; and others recommend both.[4]

Infants exposed to HSV during birth, as documented by virologic testing or presumed by observation of lesions, should be followed up carefully in consultation with a specialist. Some specialists recommend that these infants have surveillance cultures of mucosal surfaces to detect HSV infection before clinical signs of neonatal herpes develop. Some specialists also recommend the use of acyclovir for infants born to women who acquired HSV near term because the risk for neonatal herpes is high for these infants.[4]

All infants who have evidence of neonatal herpes should be promptly evaluated and treated with systemic acyclovir. The recommended regimen for infants treated for known or suspected neonatal herpes is acyclovir (20 mg/kg body weight IV every 8 hours for 21 days for disseminated and CNS disease or 14 days for disease limited to the skin and mucous membranes).[4]

The recommended infection prevention measures include Standard Precautions and in some instances Standard Precautions plus Contact Precautions. The Standard Precautions plus Contact Precautions are recommended for persons with disseminated HSV and severe primary HSV or neonatal HSV until the lesions are dry and crusted. Standard Precautions are recommended for patients with mucocutaneous recurrent (skin, oral, genital) lesions.[7]

Chancroid

Chancroid is a sexually transmitted genital ulcerative disease with worldwide distribution. It is caused by *Haemophilus ducreyi.*The prevalence of chancroid is decreasing worldwide and in the United States. Chancroid usually occurs in outbreaks but is endemic in some areas. An estimated 10 percent of people who acquire chancroid in the United States are coinfected with HSV or *T. pallidum*. An even higher percentage of persons infected outside the United States are coinfected with HSV or *T. pallidum*.[4]

Chancroid is most frequently found in uncircumcised non-Caucasian men. Women account for only 10 percent of reported cases.[14]

The incubation period is usually 5 to 7 days but may vary from 1 to several weeks. Men frequently present with one ulcer, whereas women frequently have multiple lesions. The lesions are generally confined to the genital area and perineum. A typical lesion begins as a tender papule with surrounding erythema. This papule soon becomes pustular and evolves to form a painful, sharply demarcated, nonindurated ulcer. The ulcer may be necrotic or may be surrounded by an erythematous halo. Accompanying adenopathy is usually unilateral. A characteristic inguinal bubo occurs in 50 to 60 percent of cases. The most common clinical manifestation among heterosexual men is tender unilateral inguinal or femoral lymphadenopathy. Women and homosexually active men may have proctocolitis or inflammatory involvement of perirectal or perianal lymphatic tissues that can result in fistulas and strictures. There is no asymptomatic carrier state. Chancroid has been associated with an increased risk of heterosexual HIV transmission.[14]Patients should be tested for HIV infection at the time chancroid is diagnosed.[4]

A probable diagnosis of chancroid can be made for clinical and surveillance purposes and is based on meeting all of the following criteria: (1) the patient has one or more painful genital ulcers; (2) the patient has no evidence of *T. pallidum*infection by dark-field examination of ulcer exudate or serologic test for syphilis performed at least 7 days after the onset of ulcers; (3) typical clinical presentation of genital ulcers, if present, and regional lymphadenopathy are typical for chancroid; and (4) a test for HSV performed on the ulcer exudate is negative. The combination of a painful ulcer and tender inguinal adenopathy, with supportive inguinal adenopathy, is almost pathognomonic. A definitive diagnosis requires identification of *H. ducreyi*by smear and culture of the lesion or bubo aspirate; Gram stain preparations may show Gram-negative coccobacilli in chains ("school of fish"). The special culture media for *H. ducreyi*is not widely available commercially and has a sensitivity of less than 80 percent. There is no FDA-approved PCR test for *H. ducreyi*. However, some commercial laboratories have developed their own PCR tests.[4]

The recommended treatment for chancroid is azithromycin; ceftriaxone; ciprofloxacin (contraindicated in pregnant and lactating women); or erythromycin base. The advantage of azithromycin and ceftriaxone is single-dose therapy. Patients who are circumcised respond better to treatment than do uncircumcised patients. Worldwide, some isolates with intermediate resistance to ciprofloxacin or erythromycin have been reported. Antimicrobial susceptibility testing should be performed on *H. ducreyi*that is isolated from patients who do not experience response to recommended therapies.[4]

HIV-infected patients with chancroid are more likely to have more slowly healing ulcers. They may require a longer course of treatment, and treatment failure can occur with any of the recommended regimens. Some specialists recommend a 7-day course of erythromycin for HIV-infected persons. There are limited data on the efficacy of ceftriaxone and erythromycin, so these regimens should be used for HIV-infected persons only if follow-up can be assured. Patients should be re-examined 3 to 7 days after initiation of therapy. If the ulcers have not improved within 7 days, resistance may be present. Chancroid may have been misdiagnosed, a coinfecting STD may be present, the patient may have HIV, or treatment was not taken as instructed. Male patients who are uncircumcised and patients with HIV infection have worse response to treatment than do those who are circumcised or HIV negative.[4]

HIV-infected patients who have chancroid need to be monitored closely because, in general, these patients are more likely to experience treatment failure and to have ulcers that heal more slowly. HIV-infected patients may also require longer courses of therapy than those recommended for HIV-negative patients, and treatment failures can occur with any regimen. Because evidence is limited concerning the therapeutic efficacy of the recommended ceftriaxone and azithromycin regimens in HIV-infected patients, these regimens should be used for such patients only if follow-up can be ensured. Some specialists prefer the erythromycin 7-day regimen for treating HIV infection.[4]

The amount of time it takes for the ulcers to heal completely depends on the size of the ulcer. Large ulcers may require more than 2 weeks for healing. Healing is slower for some uncircumcised men who have ulcers under the foreskin. Adenopathy resolves more slowly than ulcers. Needle aspiration or incision and drainage may be required. Although needle aspiration is an easier procedure, incision and drainage may be preferable because it avoids the need for subsequent drainage procedures.[4]

Patients should be retested 3 months after diagnosis of chancroid if the initial test results for syphilis and HIV were negative.[5]

Sexual partners encountered by the patient during the 10 days preceding the onset of symptoms should be examined and treated with a recommended regimen, regardless of the presence or absence of symptoms.[4]

Although systemic spread does not occur, chancroid may be complicated; the lesions may become secondarily infected and necrotic. Buboes may rupture, suppurate, and result in fistulas. Ulcers increase the chance of acquiring HIV infection and may cause paraphimosis or phimosis. Superinfection of ulcers may also occur and lead to destruction of the external genitalia.[14]

No adverse effects of chancroid on pregnancy outcome have been reported. However, ciprofloxacin is contraindicated during pregnancy and lactation.[4]

The recommended infection prevention measures include Standard Precautions.[7]

Pediculosis

Phthirus pubis(pubic or crab louse) is a grayish ectoparasite, measuring 1 to 4 mm. It has a segmented thorax, pointed head, and claws that help to cling to hairs. Lice often afflict those with poor hygiene, communal lifestyles, and multiple sex partners. Transmission occurs primarily through intimate physical or sexual contact.[15]

Symptoms range from slight discomfort to severe itching. Erythematous papules, nits, or adult lice (or a combination of these) clinging to pubic, perineal, or perianal hairs are present and often are noticed by patients. Pubic lice can also infest the eyelashes, eyebrows, axilla, scalp, or other body hairs. Secondary bacterial infection can occur resulting from excoriations with ensuing regional lymphadenitis.[4, 16]

Patients usually seek medical care due to the pruritus because they see the lice or nits. A presumptive diagnosis is made when a patient has a recent history of exposure and has pruritic, erythematous macules, papules, or secondary excoriations in the genital region. A diagnosis is confirmed by finding lice or nits attached to genital hairs. Patients with pediculosis pubis should be evaluated for other STDs.[4,16]

Recommended treatment regimens include permethrin (1 percent cream rinse applied to the affected areas and washed off after 10 minutes) or pyrethrins with piperonyl butoxide (nonprescription) (applied to the infested and adjacent hairy area and washed off after 10 minutes). Alternative regimens include malathion or ivermectin. Reported resistance to pediculicides has been increasing and is widespread. Malathion can be used when treatment failure is believed to have resulted from drug resistance. The odor and long duration of application for malathion make it a less attractive alternative than the recommended pediculcides. Ivermectin has been successfully used to treat lice, but it has only been evaluated in studies involving a limited number of participants. The preceding regimens should not be applied to the eyes. If the eyelashes are infected, occlusive ophthalmic ointment (i.e., petroleum jelly) should be applied to the eyelid margins (bid for 10 days). Pregnant and lactating women should be treated with either permethrin or pyrethrins with piperonyl butoxide. HIV-infected patients who have pediculosis pubis should receive the same treatment regimen as those who do not have HIV.[4,17]

Sexual partners encountered within the prior month should be treated. Patients should avoid sexual contact with their partner(s) until all have been treated and re-evaluated to rule out persistent

pediculosis pubis.[4]

Clothing or bed linen may have been contaminated and should be washed and dried by machine (hot cycle), dry cleaned, or removed from body contact for at least 72 hours. Fumigation of living areas is not necessary.[4]

Infection prevention measures include Standard Precautions plus Contact Precautions until 24 hours after treatment.[7]Healthcare personnel with pediculosis pubis should be restricted from patient contact until they have been treated and observed to be free of adult and immature lice.[15]

Scabies

The causative organism, *Sarcoptes scabiei*, is 0.3 to 0.4 mm in size. The female mite burrows under the skin to deposit eggs. The disorder is worldwide in distribution, and the United States and Europe have recently seen an increase in the number of scabies cases. This recent wave of infestations has affected people of all socioeconomic levels without regard to race, gender, age, or standards of personal hygiene. Scabies most commonly affects families, sexual partners, school-aged children, chronically ill patients, and people in communal living situations. The mode of transmission is direct skin-to-skin contact (e.g., shaking hands, wrestling, dancing), sexual contact, or from undergarments, towels, or linens. Outbreaks of scabies in a variety of healthcare settings have been increasing since 1970 in the United States.[15,17]

Symptoms include intense nocturnal itching, the presence of a pleomorphic rash that most commonly involves the hands (including interdigital areas and palms), flexor aspects of the wrists, extensor surfaces of the elbow, anterior axillary folds, extensor areas of the knees, lateral borders of the feet, ankles, toes, breasts, genitals (especially the penis and scrotum), buttocks, and abdomen (specifically the periumbilical area). Secondary bacterial infections can occur.[16]

The diagnosis is often made on clinical grounds alone. A history of exposure to a person with scabies within the preceding 2 months supports the diagnosis. Symptoms do not develop for 2 to 6 weeks in people with no prior exposure but occur rapidly for those with prior exposure. Definitive diagnosis is made by microscopic identification of the mite and its eggs, larvae, or feces from a lesion scraping.[4,16]

The recommended treatment regimens are 5 percent permethrin cream (applied to all areas of the body from the neck down and washed off after 8 to 14 hours) or ivermectin (should not be used by pregnant or lactating patients; safety in treatment of children weighing less than 15 kg has not been determined). Alternative regimens include 1 percent lindane (1 oz lotion or 30 g cream applied thinly to all body areas from the neck down and washed off thoroughly after 8 hours (not recommended for pregnant or lactating women, children younger than 2 years, or persons with extensive dermatitis; should not be used immediately after a bath or shower). Lindane is not recommended as first-line therapy because of toxicity; it should be used as an alternative only if the patient cannot tolerate other therapies or if other therapies have failed. HIV-infected patients with uncomplicated scabies should receive the same treatment regimen as patients without HIV.[4,16]

In Norwegian or crusted scabies, millions of mites inhabit the skin producing widespread disease that resembles psoriasis. Norwegian scabies are a particular risk for institutionalized patients with neurologic defects and for immunocompromised or HIV-infected patients. Other high-risk patients include those who are malnourished, those on systemic or potent topical glucocorticoids, organ transplant recipients, those

who are physically disabled, and those with various hematologic malignancies. The appropriate treatment of crusted scabies remains unclear. Substantial treatment failure may occur with single topical scabicide or ivermectin treatment. Therefore, some specialists recommend combining topical treatment with ivermectin or repeated treatments with ivermectin. In high-risk patients, special attention must be paid to the fingernails, which should be closely trimmed to reduce injury from excessive scratching. Due to the risk of neurotoxicity, lindane is not recommended for use in high-risk patients. HIV-infected and other immunosuppressed patients with crusted scabies should be treated in consultation with a specialist.[4,15,16,17]

Patients need to be warned that the rash and pruritus can persist for as long as 2 weeks after adequate therapy. Signs or symptoms occurring more than 2 weeks after treatment may be due to treatment failure, reinfection from persons or fomites, poor penetration into the skin of patients with crusted scabies, or cross-reactivity of antigens from household mites. Some specialists recommend retreatment after 1 to 2 weeks for patients who continue to have symptoms, whereas other specialists recommend retreatment only if live mites are observed. Patients with no response to the recommended treatment should be re-treated with an alternative regimen.[4]

Sexual partners, close household contacts, and close personal contacts within the preceding month should be examined and treated. Clothing or bed linens should be washed and dried by machine (hot cycle), dry cleaned, or removed from body contact for at least 72 hours. Fumigation of living areas is not necessary.[4]Routine cleaning of the environment, especially upholstered furniture, will aid in eliminating mites. Additional environmental cleaning procedures may be warranted for crusted scabies.[5, 15]

Scabies epidemics frequently occur in nursing homes, hospitals, residential facilities, and communities. Control of an epidemic can be achieved only if everyone is treated in the same 24-to-48-hour period. This approach prevents "ping-pong" infestation. An epidemic should be managed in consultation with a specialist and public health professionals.[5]

Infection prevention measures include Standard Precautions plus Contact Precautions until 24 hours after treatment is started.[7]Gloves should be worn when touching the clothing or bed linens of the infested patient. It is important for people with direct patient contact to wear long-sleeved gowns and cover the wrist area between the gloves and the gown.[15]Infected healthcare personnel should be restricted from patient contact until cleared by medical evaluation.[17]

Syphilis

Syphilis is a complex systemic illness caused by the spirochete *T. pallidum*. The organisms are slender, tightly coiled, unicellular, helical cells that are 5 to 15 µm long. Syphilis can be acquired by sexual contact, passage through the placenta (congenital syphilis), kissing or other close contact with an active lesion, transfusion of human blood, or accidental direct inoculation.[18]

In 2011, 13,970 cases of primary and secondary syphilis were reported (4.5 cases per 100,000 population). Increased incidences have mostly occurred in males, particularly in the MSM population, whereas infections have been declining in women.[1,7]

The median incubation period before clinical manifestations is 21 days with a range of 3 to 90 days. Clinically, syphilis can be divided into the following stages: incubating, primary, secondary, early latent/latency of unknown duration/late latent, and tertiary.[18]

Patients may seek treatment for signs and symptoms of primary syphilis, an ulcer or chancre at the site of infection. The chancre is characteristically a solitary, painless, indurated lesion at the site of inoculation. It may last 1 to 5 weeks and heal spontaneously. Secondary syphilis can affect nearly every organ system. Manifestations include, but are not limited to, skin rash, patchy hair loss (alopecia areata), mucocutaneous lesions, and lymphadenopathy. Condyloma latum is a flat, moist plaque found in the genital or perirectal area that is usually asymptomatic but highly infectious. Latent syphilis lacks overt clinical manifestations and can be detected by serologic testing.[4]Latent syphilis can be divided into early and late stages and also includes latency of unknown duration. For treatment purposes, the early latent period encompasses the time of infection to about 1 year after infection. During this time, the patient remains infectious, and relapses may occur. The late latent period encompasses approximately 1 year after infection, until the onset of tertiary disease.[5]Tertiary infection can encompass cardiac (aortic root aneurysm/aortic insufficiency), ophthalmic, and auditory sequelae; CNS complications (neurosyphilis); aseptic meningitis; generalized paresis; and tabes dorsalis. Gummatous lesions of the soft tissue and bone may be observed.[4]

Untreated, early syphilis in pregnant women results in perinatal death in as many as 40 percent of cases, and if acquired during the 4 years preceding pregnancy, may lead to infection of the fetus in more than 70 percent of cases.[1]Congenital syphilis—infection of the neonate acquired from an infected mother—deserves special consideration. An inflammation of the umbilical cord (necrotizing funisitis) is a characteristic finding. The clinical pattern varies, but rhinitis ("snuffles") may be present in the early infantile form, followed by a diffuse maculopapular desquamative rash. There may be generalized steochondritis and perichondritis with prominent involvement of the nose (saddle nose) and lower extremities (saber shins).[5]

Dark-field examinations and direct fluorescent antibody tests of lesion exudates or tissue are the definitive methods for diagnosis of early syphilis. A presumptive diagnosis is possible with nontreponemal tests (venereal disease research laboratory [VDRL], rapid plasma reagin [RPR]) and treponemal tests (fluorescent treponemal antibody-absorbed [FTA-ABS] or *T. pallidum*particle agglutination [TP-PA]).[4]It is important to keep in mind that one-third of patients with primary and late stage syphilis may have negative serologic findings.[5]The use of only one type of serologic test is insufficient for the diagnosis because false-positive nontreponemal test results can occur as secondary to various unrelated medical conditions, such as autoimmune conditions, older age, and injection-drug use. Nontreponemal antibody titers usually correlate with disease activity, and results should be reported quantitatively. Nontreponemal tests usually become nonreactive with time after treatment; however, in some patients, nontreponemal antibodies can persist at a low titer for a long period. Most patients who have a reactive treponemal test will remain reactive for the remainder of their lives, regardless of treatment or disease activity. Treponemal titers correlate poorly with disease activity and should not be used to assess treatment response.[4]

All patients with syphilis should be tested for HIV. Serologic tests are accurate and reliable for the diagnosis of syphilis and for following an HIV-infected patient's response to treatment. However, atypical syphilis serologic test results—whether unusually high, unusually low, or showing fluctuating titers—can

occur in HIV-infected persons. When serologic tests do not correspond with clinical findings suggestive of early syphilis, use of other tests such as a biopsy and dark-field microscopy should be considered.[4]

Patients with intact immune systems should have nontreponemal titers repeated at 6 and 12 months after treatment. If titers increase fourfold, the serologic titers fail to decrease fourfold within 12 to 24 months of therapy, or signs and symptoms attributable to syphilis develop, the patient should be treated for late latent syphilis. All patients with latent syphilis should be clinically evaluated for tertiary disease or signs of neurological sequelae. Clinical signs of neurosyphilis include cranial nerve dysfunction, meningitis, stroke, acute or chronic altered mental status, loss of vibration sense, and auditory and ophthalmic abnormalities. These symptoms require further investigation and treatment for neurosyphilis.[4]

The diagnosis of neurosyphilis usually depends on various combinations of reactive serologic test results, abnormalities of the cerebral spinal fluid (CSF) cell count or protein, or a reactive VDRL-CSF, with or without clinical manifestations.[4]

Parenteral penicillin G is the preferred drug treatment for all stages of syphilis and is the only therapy with documented efficacy for syphilis during pregnancy. Pregnant women who report a penicillin allergy should be desensitized. During the treatment of syphilis, the Jarisch-Herxheimer reaction may be observed, which is an acute febrile reaction accompanied by headache, myalgia, and other symptoms that usually occur in the first 24 hours. It is generally unresponsive to antipyretic therapy and may induce early labor or cause fetal distress. This concern should not prevent or delay therapy.[4]

For primary or secondary syphilis, a single dose of 2.4 million units of benzathine penicillin G intramuscularly is recommended. For children, 50,000 units/kg up to the adult dose of 2.4 million units in a single dose is advised. Treatment failures can occur with any regimen.[4]

Although clinical experience supports the effectiveness of penicillin for latent syphilis, limited evidence is available for guidance in choosing a specific regimen. For early latent syphilis, a single dose of 2.4 million units of benzathine penicillin G is recommended. For late latent syphilis or latent syphilis of unknown duration, three doses of 2.4 million units of benzathine penicillin in weekly doses, totaling 7.2 million units, are recommended. In children who are not allergic to penicillin, early latent syphilis is treated with benzathine penicillin G (50,000 units/kg to 2.4 million units) and should be administered as three doses at weekly intervals. In patients allergic to penicillin, the only acceptable alternatives for latent syphilis are doxycycline (100 mg bid) or tetracycline (500 mg four times per day [qid] for 28 days). The efficacy of these regimens in HIV-infected patients has not been studied. Pregnant women who are allergic should be desensitized and treated with penicillin. Tetracycline is contraindicated for pregnant women. Following treatment for latent syphilis, follow-up serologies should be obtained at 6, 12, and 24 months. If signs of treatment failure are present, the patient should be receiving three weekly doses of benzathine penicillin G.[4]

Patients with latent syphilis should be evaluated clinically for evidence of tertiary disease (e.g., aortitis and gumma) and syphilitic ocular disease (e.g., iritis and uveitis). Patients who have syphilis and who demonstrate any of the following criteria should have a prompt CSF examination:

- Neurologic or ophthalmic signs or symptoms.
- Evidence of active tertiary syphilis (e.g., aortitis and gumma)
- Treatment failure

- HIV infection with late latent syphilis or syphilis of unknown duration.[4]

The treatment for tertiary syphilis in patients who have no evidence of neurosyphilis is benzathine penicillin G (2.4 million units IM weekly for 3 weeks). Patients who are pregnant or allergic to penicillin should be treated according to the treatment regimens recommended for latent syphilis.[4]Neurosyphilis is treated with aqueous crystalline penicillin G (18 to 24 million units per day; 3 to 4 million units IV every 4 hours or by continuous infusion) for 10 to 14 days. Some specialists recommend that after completion of treatment, patients receive benzathine penicillin G (2.4 million units weekly for an additional 3 weeks). An alternative regimen of procaine penicillin (2.4 million units IM daily) plus probenecid (500 mg PO bid), both for 10 to 14 days, can be employed if compliance is ensured.[4]If CSF pleocytosis was present initially, a CSF examination should be repeated every 6 months until the cell count is normal. Patients who have neurosyphilis should be tested for HIV.

Many specialists recommend treating patients who have evidence of auditory disease caused by syphilis in the same manner as patients who have neurosyphilis, regardless of CSF examination results. Although systemic steroids are used frequently as adjunctive therapy for otologic syphilis, they have not been proven beneficial.[4]HIV-positive patients who have syphilis may be at increased risk for neurologic complications. The magnitude of these risks is not well defined. Patients with late latent syphilis or syphilis should have a CSF examination to evaluate for neurosyphilis. Some experts also recommend that HIV-infected patients with an RPR titer of at least 1:32 or a CD4 count of up to 350 should have a CSF examination. The treatment of all stages of syphilis is the same for patients with and those without HIV. HIV-infected patients who are treated for primary or secondary syphilis should be followed up clinically and serologically for treatment failure at 3, 6, 9, 12, and 24 months. HIV-infected patients who are treated for latent syphilis should be followed up clinically and with serology at 6, 12, 18, and 24 months. The appearance of any clinical symptoms or the failure of the RPR titer to decline fourfold by 12 to 24 months should prompt a repeat CSF exam to guide further treatment. The efficacy of alternative regimens has been studied only in small trials. Ceftriaxone may be effective for the treatment of syphilis in HIV-infected persons if close follow-up is assured. The dose and duration of ceftriaxone therapy is unclear.[4,19]

Between 2008 and 2011, the rate of congenital syphilis decreased by almost 20 percent. In 2011, 360 or 8.5 cases of congenital syphilis were reported per 100,000 live births in the United States.

STD Trends

Infants with congenital syphilis should be treated with aqueous crystalline penicillin G (50,000 units/kg/dose IV every 12 hours for the first 7 days of life and every 8 hours thereafter for a total of 10 days).[5]Infants and children who require treatment for syphilis but who have a history of penicillin allergy or develop an allergic reaction presumed secondary to penicillin should be desensitized, if necessary, and then treated with penicillin.[4]

For identification of at-risk sexual partners, the periods before treatment are (1) 3 months plus duration of symptoms for primary syphilis; (2) 6 months plus duration of symptoms for secondary syphilis; and (3) 1 year for early latent syphilis. Sexual transmission of *T. pallidum*occurs only when mucocutaneous syphilitic lesions are present. The presence of these lesions is uncommon after the first year of infection. However, persons exposed sexually to a patient who has syphilis in any stage should be

evaluated clinically and serologically and treated with a recommended regimen, according to the recommendations provided below:[4]

- Persons who were exposed within the 90 days preceding the diagnosis of primary, secondary, or early latent syphilis in a sex partner may be infected even if seronegative and should be treated presumptively.[4]
- Persons who were exposed more than 90 days before the diagnosis of primary, secondary, or early latent syphilis in a sex partner should be treated presumptively if the serologic test results are not available immediately and the opportunity for follow-up is uncertain.[4]
- For purposes of partner notification, and presumptive treatment of exposed sex partners, patients with syphilis of unknown duration who have high nontreponemal serologic test titers (i.e., 1:32), can be assumed to have early syphilis. However, serologic titers should not be used to differentiate early from late latent syphilis for the purpose of determining treatment.[4]
- Long-term sex partners of patients who have latent syphilis should be evaluated clinically and serologically for syphilis and treated on the basis of the evaluation findings.[4]

The recommended infection prevention measures include Standard Precautions.[7]

VAGINITIS

Vaginitis is usually characterized by a vaginal discharge or vulvar itching and irritation. A vaginal odor may be present. Three main clinical entities cause vaginitis: trichomoniasis, vulvovaginal candidiasis, and bacterial vaginosis. Trichomoniasis is sexually transmitted, whereas candidiasis usually is not. The role of sexual transmission is unknown in bacterial vaginosis.[4]

Trichomoniasis

Trichomoniasis is caused by *T. vaginalis*, a motile, flagellated protozoan that can infect the urogenital tract in both women and men. An estimated 7.4 million cases of trichomoniasis occur in men and women each year.[20]

The clinical presentation in females includes diffuse, malodorous, yellow-green vaginal discharge, pruritus, vulvar irritation, and lower abdominal discomfort. The symptoms may become worse with menstruation, and the patient may also complain about dysuria. In males, urethritis may occur. However, some women and many men have no symptoms.[20]Some men with *T. vaginalis*have NGU.[4]

Diagnosis is made by microscopic examination of a wet preparation of vaginal secretions; a drop of secretion is placed on a slide (a drop of saline may be added if the secretion is thick) and quickly examined for the motile trichomonads. The sensitivity of the wet prep is approximately 60 to 70 percent. Two point-of-care tests have recently been approved by the FDA: The OSOM *Trichomonas*rapid test is an immunochromatographic capillary flow dipstick test that can be performed on vaginal secretions, and the Affirm VP III is a nucleic acid probe that detects *T. vaginalis,Gardnerella vaginalis*, and *Candidaalbicans*. The culture remains the most sensitive commercially available diagnostic test for trichomoniasis. The culture should be employed if trichomoniasis is suspected but not confirmed by microscopy. In men, wet preparation is insensitive, and culture testing of urethral swab, urine, and semen is required for optimal sensitivity.[4]

Patients with *T. vaginalis*should be screened for other STDs such as *N. gonorrhoeae*, *C. trachomatis*, and HIV. The inflammatory response to trichomoniasis may increase the risk of HIV transmission.[20]

Trichomoniasis increases the incidence of premature rupture of membranes, preterm delivery, and low-birth weight. Pregnant women should be treated to relieve the symptoms; however, data have not shown that treating pregnant women with no symptoms reduces the risk of adverse pregnancy outcomes related to *T. vaginalis*.[4]Approximately 2 to 17 percent of the female offspring of infected women acquire trichomoniasis, probably through transmission as the neonate passes through the infected birth canal.[20]

The recommended treatment regimens are metronidazole (2 g PO in a single dose) or tinidazole (2 g PO in a single dose). Metronidazole 500 mg given orally bid for 7 days is an alternative regimen, but intravaginal metronidazole gel is not recommended. Pregnant women may be treated with a single 2-g oral dose of metronidazole (pregnancy category B). Tinidazole is pregnancy category C, and its safety in pregnancy has not been well evaluated. A consistent association between the use of metronidazole during pregnancy and fetal harm or birth defects has not been demonstrated. Exposure of nursing infants to metronidazole and tinidazole can be reduced by not nursing for 12 to 24 hours after the last dose of metronidazole or for 72 hours after the last dose of tinidazole. Patients with HIV and trichomoniasis should receive the same treatment regimen as patients who do not have HIV. Because metronidazole has a disulfiram (Antabuse) effect, alcohol should not be consumed during administration or until 24 hours after treatment is completed. Patients should not consume alcohol while on tinidazole and should continue to abstain for 72 hours after treatment is completed.[4]

The incidence, persistence, and recurrence of trichomoniasis in HIV-infected women are not correlated with immune status.[4]Follow-up visits are unnecessary if symptoms resolve. If treatment failure occurs after a single dose of metronidazole, the patient should be re-treated with metronidazole (500 mg bid for 7 days) or tinidazole (2 g PO in a single dose). If treatment fails repeatedly, the patient can be treated with metronidazole (2 g PO daily for 5 days) or tinidazole (2 g PO daily for 5 days). Patients with laboratory-documented *T. vaginalis*infections who have no response to 5 days of treatment and have not been reinfected should be treated in consultation with an expert, and evaluation of the susceptibility of *T. vaginalis*to metronidazole and tinidazole should be done. Consultation is available from the CDC.[4]

Contacts must receive treatment or the disease may recur. Patients should be instructed to avoid sexual contact until they and their partners are cured. A cure is defined as the absence of symptoms after completion of treatment; this can also be verified by a microbiologic test.[4]

The recommended infection prevention measures include Standard Precautions.[7]

Vulvovaginal Candidiasis

Vulvovaginal candidiasis (VVC) is most frequently caused by the yeast *C.albicans*. Other *Candida*or *Torulopsis*species may occasionally be present. Antibiotic use can precipitate VVC in women who have vaginal *Candida*colonization.[4]VVC is also frequently seen during pregnancy and in patients with diabetes mellitis.[21]However, the majority of healthy women with uncomplicated VVC have no identifiable precipitating factors. VVC can occur concomitantly with STDs.[4]

An estimated 75 percent of women will have at least one episode of VVC, 40 to 45 percent will have two or more episodes, and 5 percent will have four or more episodes per year. Although the incidence of VVC in HIV-infected women remains unknown, vaginal *Candida*colonization rates among HIV-infected women are higher than those among uninfected women with similar demographic characteristics and high-risk behaviors. The colonization rate for HIV-infected women correlates with increasing severity of immunosuppression. Symptomatic VVC is more common in HIV-infected women and similarly correlates with severity of the immunodeficiency. The typical clinical presentation of marked pruritus, dyspareunia, external dysuria, vaginal soreness, and "cottage cheese-like" vaginal discharge is not specific for VVC. The VVC is classified as uncomplicated or complicated based on the clinical presentation, microbiology, and host factors. Uncomplicated VVC is sporadic or infrequent, mild to moderate, likely to be due to *C. albicans*, and in an immunocompetent host. Approximately 10 percent of women will have complicated VVC. Complicated VVC is defined as recurrent, severe, or non-*albicans*candidiasis and occurs in women with uncontrolled diabetes, debilitation, immunosuppression, or during pregnancy.[4]

The diagnosis of uncomplicated VVC is suggested clinically by external dysuria and vulvar pruritus, pain, swelling, and redness and erythema in the vulvovaginal area.[4]

Signs include a white, thick, curdy vaginal discharge, vulvar edema, fissures, or excoriations. The diagnosis can be made by placing a sample of vaginal secretions on a slide and adding a drop of 10 percent potassium hydroxide (KOH). The KOH dissolves other cell material and debris and allows the yeast forms to be seen easily during microscopic examination. A Gram stain of the vaginal discharge can also be done to see the yeast or pseudohyphae. For a woman with negative wet mounts, vaginal cultures for *Candida*should be considered if she has any signs or multiple symptoms. If *Candida*cultures cannot be done, empiric treatment can be considered for women with symptoms and any sign of VVC on examination when the wet mount is negative. Because 10 to 20 percent of women are colonized with vaginal *Candida*species and other yeasts, a positive culture without signs or symptoms is not an indication for treatment.[4]

Uncomplicated VVC is effectively treated locally with short-course topical formulations (i.e., single dose and regimens of 1 to 3 days). The topically applied azole drugs are more effective than nystatin. Treatment with azoles results in relief of symptoms and negative cultures in 80 to 90 percent of patients who complete therapy. VVC frequently occurs during pregnancy. Only topical azole therapies, applied for 7 days, are recommended for use among pregnant women. Among HIV-infected women, systemic azole exposure is associated with the isolation of non-*albicansCandida*species from the vagina.[4]

The CDC lists 14 different topical regimens that may be used. It is important to note that the creams and suppositories recommended are oil-based and may weaken latex condoms and diaphragms. Fluconazole (150 mg PO given in a single dose), an oral agent, is also a recommended therapy. Only topical azole therapies, applied for 7 days, are recommended for use in pregnant women. Intravaginal preparations of butaconazole, clotrimazole, miconazole, and tioconazole are available over-the-counter (OTC), whereas fluconazole requires a prescription. However, unnecessary or inappropriate use of OTC preparations is common and may cause a delayed treatment of other causative agents for vulvovaginitis, which could result in adverse clinical outcomes.[4]

Treatment of HIV-infected women with VVC is the same as that for HIV-seronegative women. Women with underlying debilitating medical conditions (e.g., uncontrolled diabetes or those undergoing corticosteroid treatment) do not have good response to short-term therapies. Efforts should be made to

correct modifiable conditions, and prolonged (e.g., 7 to 14 days) conventional antimycotic therapy is necessary.[4]

Topical agents do not usually cause systemic side effects, though they may cause local burning or irritation. Oral agents may cause nausea, abdominal pain, and headache. Oral azoles have been rarely associated with abnormal elevations of liver enzymes. Clinically important interactions may occur when these oral agents are administered with other drugs, including astemizole, calcium channel antagonists, cisapride, coumadin, cyclosporin A, oral hypoglycemic agents, phenytoin, protease inhibitors, tacrolimus, terfenadine, theophylline, trimetrexate, and rifampin. Follow-up is unnecessary unless symptoms persist or recur within 2 months of the initial onset of symptoms.[4]

VVC is not usually acquired through sexual intercourse, so treatment of partners is not recommended. However, a minority of male sexual partners may have balanitis and may benefit from treatment with topical antifungal agents to relieve symptoms.[4]

Recurrent VVC, defined as four or more episodes of symptomatic VVC in 1 year, affects less than 5 percent of women and is defined as more than four episodes of symptomatic VVC each year. *C. glabrata*and other non-*albicansCandida*species are found in 10 to 20 percent of these patients. Vaginal cultures are needed so that unusual species such as *C. glabrata*can be identified. Compared with *C. albicans, C. glabrata*does not form hyphae or pseudohyphae and is not easily distinguished on microscopy. The treatment of recurrent VVC involves an extended course of therapy (e.g., 7 to 14 days of topical therapy or a 150-mg dose of fluconazole repeated 3 days later) to achieve mycologic remission before starting maintenance antifungal treatment. The first-line maintenance antifungal regimen is fluconazole (100 mg, 150 mg, or 200 mg PO weekly for 6 months). Topical clotrimazole (200-mg vaginal suppositories twice weekly or 500-mg vaginal suppositories once weekly for 6 months) or other intermittently dosed topical therapies also can be used.[4]

Based on available data, VVC treatment in HIV-infected women should not differ from that for uninfected women. Although long-term prophylactic therapy with fluconazole, at a dose of 200 mg weekly, has been effective in reducing *C. albicans*colonization and symptomatic VVC, this regimen is not recommended for routine primary prophylaxis in HIV-infected women without recurrent VVC. Given the frequency at which recurrent VVC occurs in the immunocompetent healthy population, the occurrence of recurrent VVC should not be considered an indication for HIV testing.[4]

Severe VVC presents as extensive vulvar erythema, edema, excoriation, and fissure formation. The recommended treatment is 7 to 14 days of topical azole or oral fluconazole in two sequential doses with the second dose given 72 hours after the initial dose.[4]

Treatment of non-*albicans*VVC is not as clear-cut. The optimal treatment regimen remains unknown. Options include longer duration of therapy (7 to 14 days) with a nonfluconazole azole drug (oral or topical) as first-line therapy. If recurrence occurs, 600 mg of boric acid in a gelatin capsule is recommended, administered vaginally once daily for 2 weeks. This regimen has clinical and mycologic eradication rates of approximately 70 percent. If symptoms recur, referral to a specialist is advised.[4]

The recommended infection prevention measures include Standard Precautions.[7]

Bacterial Vaginosis

Bacterial vaginosis (BV), formerly called nonspecific vaginitis, is a clinical syndrome characterized by replacement of the normal H_2O_2-producing vaginal *Lactobacillus*species with high concentrations of anaerobic bacteria (*Prevotella*species and *Mobiluncus*species), *G. vaginalis*, and *M. hominis*. BV is the most common cause of vaginal discharge and malodor; however, as many as 50 percent of women with BV may report no symptoms.[4]

BV is associated with having multiple sex partners, a new sex partner, douching, and lack of vaginal lactobacilli. It remains uncertain if BV results from acquisition of a sexually transmitted pathogen. Women who have never been sexually active are rarely affected. Treatment of male sex partners has not been beneficial in preventing the recurrence of BV.[4]

The clinical presentation includes a complaint of mild to moderate vaginal discharge. The discharge is usually thin and homogenous. The inflammation and irritation are much less severe than in VVC or trichomoniasis.[22]The following criteria are used to make the diagnosis: (1) vaginal pH greater than 4.5; (2) unpleasant, fishy odor is present either before or after 10 percent KOH is added to vaginal secretions (the whiff test); (3) a wet mount of vaginal secretions shows epithelial cells covered with bacteria ("clue cells"); and (4) homogeneous, white, noninflammatory discharge that smoothly coats the vaginal walls. The gold standard diagnostic test is a Gram stain for examination of the bacterial flora showing paucity of lactobacilli and predominance of Gram-negative organisms. Culture for *G. vaginalis*is not recommended. However, a DNA probe (Affirm VP III) test for high concentrations of *G. vaginalis*may have utility. The cervical Pap tests have limited sensitivity in diagnosing BV. Other commercially available tests that may be useful to diagnose BV include card testing to detect elevated pH and trimethylamine or proline aminopeptidase. However, card testing has low sensitivity and specificity and therefore is not recommended. PCR also has been used in research settings, but its clinical utility is uncertain.[4]

BV during pregnancy is associated with adverse outcomes, including premature rupture of membranes, preterm labor, preterm birth, amnionitis, late-term miscarriage, and postpartum endometriosis. There is an increased risk of endometritis, salpingitis, and posthysterectomy vaginal cuff infection.[22]

Diagnosis of BV is based on clinical criteria or a Gram stain. To make the diagnosis using clinical criteria, three of the following symptoms or signs must be present:

- Homogeneous, thin, white discharge that smoothly coats the vaginal walls
- Presence of clue cells on microscopic examination
- pH of vaginal fluid greater than 4.5
- A fishy odor of vaginal discharge before or after addition of 10 percent KOH (i.e., the whiff test)[4]

The gold standard when using a Gram stain is to determine the relative concentration of lactobacilli (long Gram-positive rods), Gram-negative and Gram-variable rods and cocci (i.e., *G. vaginalis, Prevotella, Porphyromonas*, and peptostreptococci), and curved Gram-negative rods *(Mobiluncus)*characteristic of BV. Other commercially available tests that may be useful for the diagnosis of BV include a card test for the detection of elevated pH and trimethylamine and proline aminopeptidase.[4]

The goal of treatment is to relieve the signs and symptoms and to reduce the risk for infectious complications after an abortion or hysterectomy. All women with symptomatic disease require treatment,

regardless of pregnancy status. More information is needed before recommending treatment for all pregnant women with asymptomatic disease.[4]

Recommended regimens include metronidazole; 2 percent clindamycin cream; or metronidazole gel 0.75 percent. Note: Patients should be advised to avoid consuming alcohol during treatment with metronidazole and for 24 hours thereafter. Clindamycin cream is oil based and may weaken latex condoms and diaphragms for 5 days after use. In addition, topical clindamycin preparations should not be used in the second half of pregnancy.[4]

Alternative regimens include clindamycin, clindamycin ovules intravaginally once at bedtime for 3 days, tinidazol, or tinidazol PO daily for 5 days. Additional alternative regimens include metronidazole, or a single dose of clindamycin intravaginal cream, though data on the performance of these alternative regimens are limited.[4]

In pregnant women, systemic therapy may be preferable to treat possible subclinical upper-tract infections (metronidazole or clindamycin).[4]Due to an increased risk of preterm birth, clindamycin cream is not recommended for pregnant patients.[22]HIV-infected patients with BV should receive the same treatment regimen as patients without HIV. BV appears to be more persistent in HIV-positive women.[4,5]

Consideration should be given to screening and treating symptomatic or asymptomatic BV before surgical abortion or hysterectomy procedures are performed.[4]

The use of lactobacillus intravaginal suppositories to restore normal flora and treat BV has been evaluated in several studies. The clinical and microbiologic efficacy of using these suppositories was assessed. However, no currently available lactobacillus suppository was determined to be better than placebo 1 month after therapy for either clinical or microbiologic cure. No data support the use of douching for treatment or relief of symptoms.[4]

BV has been associated with adverse pregnancy outcomes (e.g., premature rupture of the membranes, chorioamnionitis, preterm labor, preterm birth, intra-amniotic infection, postpartum endometritis, and postcesarean wound infection). Therefore, all pregnant women who have symptomatic disease should be treated. Some specialists prefer using systemic therapy to treat possible subclinical upper genital tract infections.[4]

Treatment of BV in asymptomatic pregnant women at high risk for preterm delivery (i.e., those who have previously delivered a premature infant) with a recommended oral regimen has reduced preterm delivery in three of four randomized controlled trials. Some specialists recommend screening and oral treatment of these women. However, the optimal treatment regimens have not been established. If screening is conducted, screening and treatment should be performed during the first prenatal visit.[4]

The recommended regimens for pregnant women are metronidazole or clindamycin. Note that intravaginal clindamycin cream should be used during only the first half of pregnancy.[4]

The follow-up visits are unnecessary if symptoms resolve. However, evaluation of pregnant women 1 month after completion of the therapy should be considered to make sure that treatment was effective. Routine treatment of sexual partners is not recommended.[4]

The recommended infection prevention measures include Standard Precautions.[7]

Lymphogranuloma venereum

Lymphogranuloma venereum (LGV) is caused by *C. trachomatis* serovars L1, L2, or L3. These strains are distinct from those that cause NGU. In many parts of the world, including Asia, Africa, and South America, LGV is endemic; it occurs sporadically elsewhere. However, LGV is rare in the United States where it occurs predominantly among MSM. Lack of universal screening and reporting means that reliable incidence and prevalence data for the United States are unavailable.[4,5]

LGV is the only *C. trachomatis* infection that causes constitutional symptoms. In the first phase, a small, painless, herpetiform vesicle, nonindurated papule, or ulcer may develop locally. However, the lesions may have disappeared by the time the patient presents for evaluation. This lesion is followed by inguinal or perirectal lymphadenopathy or bubo, fever, and other constitutional symptoms. The third phase of illness is characterized by lymph node suppuration, abscess, lymphedema, ulceration, or fistula formation, or a combination of these. The most common clinical manifestation among heterosexual men is tender, usually unilateral, inguinal or femoral unilateral lymphadenopathy. Sexually active women and MSM may have proctocolitis (including mucoid or hemorrhagic rectal discharge, anal pain, constipation, fever, or tenesmus) or inflammatory involvement of perirectal or perianal lymphatic tissues that can result in fistulas and strictures.[4,5] LGV is an invasive, systemic infection. If LGV proctocolitis is not treated early, it may lead to chronic, colorectal fistulas and strictures. Genital and colorectal LGV lesions may also develop secondary bacterial infection or be coinfected with other sexually and nonsexually transmitted pathogens.[4]

Diagnosing LGV is a challenge. The differential diagnosis includes syphilis, genital herpes, donovanosis, and chancroid. Excluding other causes of genital ulcers or inguinal lymphadenopathy usually makes the diagnosis. The clinical suspicion can be supported by identification of *C. trachomatis* from infected tissue (genital and lymph node lesion swab or bubo aspirate) specimens by culture, direct immunofluorescence, or NAAT. Chlamydia serologies of 1:64 or higher also support the diagnosis in the appropriate clinical scenario. The NAATs for *C. trachomatis* are not FDA cleared for testing rectal specimens. The methods for differentiating LGV-associated *C. trachomatis* strains from non-LGV strains exist but are not often used. Molecular procedures (such as PCR-based genotyping) can be used to differentiate LGV from non-LGV *C. trachomatis.* However, these tests are not widely available.[4]

In the absence of specific LGV diagnostic testing, patients with a clinical syndrome consistent with LGV, including proctocolitis or genital ulcer disease with lymphadenopathy, should be treated for LGV.[4]

The treatment cures LGV and prevents ongoing tissue damage. Fluctuant buboes should be aspirated through normal skin or incision and drainage to prevent the formation of inguinal/femoral ulcerations. The recommended antimicrobial regimen for LGV is doxycycline (100 mg PO bid for at least 21 days; contraindicated for pregnant women). Alternative regimens include erythromycin base (500 mg PO qid for 21 days). Some specialists believe that azithromycin (1 g PO once weekly for 3 weeks) is likely to be effective, but clinical data are lacking. Doxycycline is contraindicated in pregnant women. Pregnant and lactating women should be treated with erythromycin. Azithromycin may be useful in this instance, but no published safety or efficacy data are available. Patients should be followed up clinically until signs and symptoms resolve. Anecdotal evidence suggests that HIV-infected patients may require prolonged therapy, and resolution may be delayed.[4]

HIV-positive patients with LGV should be treated with the same regimens as those who are HIV negative. However, a longer duration of therapy may be necessary, and delay in resolution of symptoms might occur.[4]

Sexual partners should be examined, tested for urethral or cervical chlamydial infection, and treated if sexual contact occurred during the 30 days preceding onset of the patient's symptoms.[4]

The recommended infection prevention measures include Standard Precautions.[7]

Granuloma Inguinale (Donovanosis)

Donovanosis is a genital ulcer disease caused by *Klebsiellagranulomatis*(formerly *Calymmatobacteriumgranulomatis*). Although rare in the United States, it is endemic in many tropical and developing regions, including India, southern Africa, central Australia, and Papua New Guinea.[4]

Donovanosis is characterized by progressive painless ulcers without adenopathy. The ulcers have rolled edges, look "beefy red," are very vascular, and tend to bleed easily. The clinical presentation also can include hypertrophic, necrotic, or sclerotic variants. Adenopathy and pain may be present if the ulcers become secondarily infected. Visualizing "Donovan bodies" on biopsy or tissue crush preparation makes diagnosis. *K.granulomatis*is difficult to culture. No PCR tests are FDA approved for diagnosis.[4]

Treatment is effective and stops disease progression. Healing typically proceeds inward from the ulcer margins. Prolonged therapy is usually needed to allow granulation and re-epithelialization of the ulcers. Relapses may occur for as long as 18 months.[4]

The recommended regimen is doxycycline (100 mg PO bid for 3 weeks or until lesions heal). Several alternative regimens exist, including azithromycin (1 g PO weekly for 3 weeks), ciprofloxacin (750 mg PO bid for 3 weeks), erythromycin base (500 mg PO bid for 3 weeks), and trimethoprim/sulfamethoxazole DS (1 tablet PO bid for 3 weeks). All regimens should be continued until the lesions have healed. If healing does not start after several days of treatment, some experts recommend adding an aminoglycoside (i.e., gentamicin 1 mg/kg IM/IV every 8 hours). Doxycycline is contraindicated in pregnancy, so erythromycin base (500 mg PO qid) should be used in pregnant patients and an aminoglycoside should be strongly considered.[4]

HIV-infected patients with donovanosis should receive the same regimens as those who do not have HIV. Consideration should be given to the addition of a parenteral aminoglycoside (e.g., gentamicin).[4]

It is important to note that pregnancy is a relative contraindication to the use of sulfonamides and that doxycycline and ciprofloxacin are contraindicated in pregnant women. Pregnant and lactating women should be treated with the erythromycin regimen, and consideration should be given to the addition of a parenteral aminoglycoside (e.g., gentamicin). Azithromycin may prove useful for treating granuloma inguinale during pregnancy, but published data are lacking.[4]

Sexual contacts within the previous 60 days should be examined and offered treatment. Therapy in the absence of symptoms is of unproven benefit.[4]

The recommended infection prevention measures include Standard Precautions.[7]

Epididymitis

Epididymitis can be caused by a variety of organisms. *C. trachomatis*or *N. gonorrhoeae*are common etiologic agents for acute epididymitis among sexually active men younger than 35 years. Acute epididymitis caused by sexually transmitted enteric organisms (e.g., *Escherichia coli*) also occurs among men who are the insertive partner during anal intercourse. Fungi and mycobacteria are more likely to cause acute epididymitis in immunosuppressed patients than in immunocompetent patients.[4]

Urethritis is usually seen with sexually transmitted acute epididymitis. In these patients, the urethritis is frequently asymptomatic and is rarely, if ever, accompanied by bacteriuria.[4]

Sexually transmitted epididymitis is uncommon among men older than 35 years. However, bacteriuria secondary to obstructive urinary disease is relatively common with nonsexually transmitted epididymitis in this age group associated with urinary tract instrumentation or surgery, systemic disease, or immunosuppression.[4]

Acute epididymitis is a clinical syndrome consisting of pain, swelling, and inflammation of the epididymis of less than 6 weeks' duration. The acute epididymitis typically includes unilateral testicular pain and tenderness. Hydrocele and palpable swelling of the epididymis usually are present. Although the inflammation and swelling usually begin in the tail of the epididymis, they can spread to involve the rest of the epididymis and testicle. The spermatic cord is usually tender and swollen.[4]

Chronic epididymitis is characterized by a 3-month or longer history of symptoms of discomfort or pain in the scrotum, testicle, or epididymis that is localized on clinical examination. Chronic epididymitis has been subcategorized into inflammatory chronic epididymitis, obstructive chronic epididymitis, and chronic epididymalgia.[4]

Testicular torsion is a surgical emergency that should be considered in all cases of acute epididymitis. However, testicular torsion occurs more frequently among adolescents and in men without evidence of inflammation or infection. Emergency testing for torsion may be indicated when the onset of pain is sudden, pain is severe, or the test results available during the initial examination do not support a diagnosis of urethritis or urinary tract infection. If the diagnosis is questionable, a specialist should be consulted immediately because testicular viability may be compromised. Radionuclide scanning of the scrotum is the most accurate radiologic method of diagnosis, though it is not routinely available. The color duplex Doppler ultrasonography has a sensitivity of 70 percent and a specificity of 88 percent in diagnosing acute epididymitis.[4]

The evaluation of epididymitis should include either of the following:

- Gram stain of urethral secretions demonstrating at least five white blood cells (WBCs) per oil-immersion field. The Gram stain is the preferred rapid diagnostic test for evaluating urethritis. It is highly sensitive and specific for documenting both urethritis and the presence or absence of gonococcal infection. The gonococcal infection is established by documenting the presence of WBC-containing intracellular Gram-negative diplococci on urethral Gram stain.[4]
- Positive leukocyte esterase test on first-void urine or microscopic examination of first-void urine sediment demonstrating at least 10 WBCs per high-power field.[4]

Culture, nucleic acid hybridization tests, and nucleic acid amplification tests are available for the detection of both *N. gonorrhoeae*and *C. trachomatis*. The culture and nucleic acid hybridization tests require urethral swab specimens, whereas amplification tests can be performed on urine specimens. Because of their higher sensitivity, amplification tests are preferred for the detection of *C. trachomatis*. Depending on the risk, patients whose conditions have been diagnosed as a new STD should receive testing for other STDs.[4]

The majority of patients can be treated on an outpatient basis. Hospitalization should be considered when severe pain suggests other diagnoses, such as testicular torsion, testicular infarction, or abscess. Hospitalization should also be considered when patients are febrile or may not adhere to an antimicrobial regimen.[4]

Empiric therapy is indicated before laboratory test results are available. The goals of treatment of acute epididymitis caused by *C. trachomatis*or *N. gonorrhoeae*are (1) microbiologic cure of infection, (2) improvement of signs and symptoms, (3) prevention of transmission to others, and (4) a decrease in potential complications, such as infertility or chronic pain. As an adjunct to therapy, bed rest, scrotal elevation, and analgesics are recommended until fever and local inflammation have subsided.[4]

The recommended regimen for acute epididymitis that is most likely caused by *C. trachomatis*or *N. gonorrhoeae*is ceftriaxone IM in a single dose plus doxycycline orally for 10 days. The recommended regimen for acute epididymitis that is most likely caused by enteric organisms, or for patients' allergic to cephalosporins or tetracyclines, is ofloxacin orally for 10 days or levofloxacin orally once daily for 10 days. Patients who have uncomplicated acute epididymitis and also have HIV should receive the same treatment regimen as patients who do not have HIV.[4]

Patients who do not experience improvement within 3 days of the initiation of treatment require re-evaluation of both the diagnosis and therapy. The swelling and tenderness that persist after completion of antimicrobial therapy should be evaluated comprehensively. The differential diagnosis includes tumor, abscess, infarction, testicular cancer, tuberculosis, and fungal epididymitis.[4]

Patients with acute epididymitis that is confirmed or suspected to be caused by *N. gonorrhoeae*or *C. trachomatis*should be instructed to refer sex partners for evaluation and treatment if their contact with the index patient was within the 60 days preceding onset of the patient's symptoms. Patients should be instructed to avoid sexual intercourse until they and their sex partners are cured, which is defined as the completion of therapy with the patient and partners no longer having symptoms.[4]

The recommended infection prevention measures include Standard Precautions.[7]

STDs and HIV

STDs increase the likelihood of both transmitting and acquiring HIV. Individuals with STDs are three to five times more likely to acquire HIV if exposed to the virus through sexual contact than are noninfected individuals. In addition, if an HIV-infected individual also has an STD, he or she is three to five times more likely than other HIV-infected persons to transmit HIV through sexual contact.[23,24]

STDs facilitate the transmission of HIV, the contraction of HIV, or both. Studies show that *C. trachomatis*and *T. pallidum*lipoproteins increase HIV replication. The STD pathogens may disrupt the mucosal tissue, increase the number of cells receptive to HIV, or increase the number of receptors

expressed per cell. Elevated levels of HIV-1 RNA in semen have been found in patients with gonorrhea, trichomoniasis, and genital ulcers. Elevated levels of HIV-1 DNA have been found in cervicovaginal specimens from patients with gonorrhea, chlamydia, cervicovaginal ulcer, or cervical mucus.[24]Men who have gonorrhea and HIV are more than twice as likely to have HIV in their genital secretions, and the median concentration of HIV in their semen is as much as 10 times greater than that for coinfected men. The higher the concentration of HIV in semen or genital fluids, the more likely it is that HIV will be transmitted to a sex partner.

STDs also appear to increase susceptibility through breaks in the skin. Genital ulcers such as those present in syphilis, herpes, and chancroid create a portal of entry for HIV. In addition, inflammation resulting from genital ulcers or nonulcerative STDs, such as chlamydia, gonorrhea, and trichomoniasis, increase the concentration of cells in genital secretions that can serve as targets for HIV (e.g., CD_4+ cells).[25]

Detecting and treating STDs can substantially reduce HIV transmission. Treating STDs in HIV-infected individuals decreases both the amount of HIV in genital secretions and how frequently HIV is found in those secretions, thereby decreasing the risk of transmission.[26]Early detection and treatment of curable STDs should become a major, explicit part of a comprehensive HIV prevention program.[25]

GYNECOLOGY

Gynecologic Flora

To understand the etiology of gynecologic infections, it is important to know the normal flora of the female reproductive tract. The lower part of the reproductive tract is heavily colonized by bacteria. Anaerobes are 10 times more common in the vagina than aerobes.[27]Normal vaginal flora commonly includes lactobacilli, various species of streptococci, *G. vaginalis*, strains of Enterobacteriaceae, and anaerobes. A number of naturally occurring events can alter the vaginal flora. During pregnancy, lactobacilli and yeasts increase in the vagina while other bacteria, especially anaerobes, decrease. At the time of delivery, the anaerobic population is increasing, and by 6 weeks after delivery, the vaginal flora returns to the prepartum distribution.[27]

The vaginal flora is also affected by menopause. Women who receive estrogen treatment have increased numbers of lactobacilli and diphtheroids. Women who are not receiving estrogen treatment have a higher ratio of anaerobes. Postmenopausal women have a lower risk of infection after vaginal procedures, such as hysterectomy, than do women of reproductive age.[27]

Other factors also affect vaginal flora. For example, *Bacteroides fragilis*and aerobes (especially *E. coli*, *Klebsiella*, *Enterobacter*, and enterococci) increase within 5 days after abdominal or vaginal hysterectomy.[28,29]Hospitalization can result in more virulent vaginal organisms, including enterococci, *B. fragilis*, and resistant Enterobacteriaceae. Antimicrobial therapy reduces the normal flora, thus allowing amplification of yeast growth. An increased number of *E. coli*are seen in patients with invasive cancer. Douching monthly or more frequently is associated with an increase in bacterial vaginosis because it disrupts the normal flora. An increase in *G. vaginalis*and *M. hominis*has been found, as well as a lack of hydrogen peroxide–producing lactobacilli.[30]The alterations of the female reproductive system that increase the risk of infection are presented in Table 91-1.

Table 91-1 Alterations of the Female Reproductive System That Increase Risk of Infection

Alterations	Example	Mechanism
Obstruction	Congenital anomalies such as imperforate hymen; neoplasms; foreign bodies, such as tampons, diaphragms or pessaries.	Interrupts normal flow of fluids (e.g., blood); stagnation of fluids provides media for microbial growth; tampon use may be associated with toxic shock syndrome.
Trauma	Surgery, abortions, sexual abuse.	Mucosal surfaces may be disrupted, enhancing microbial attachment and penetration, alters or impedes blood supply, devitalized tissue provides bacterial growth medium; skin defenses (such as acidity) are destroyed. Recommendations on management of possible sexual exposure to HIV have been published.
Impaired host defenses	Antimicrobial therapy; presence of bacterial vaginosis may increase risk of infection following hysterectomy.	Change in vaginal flora or pH may allow pathogens to proliferate and alter ability of mucosa to resist microbial penetration; consider screening and treatment for bacterial vaginosis before elective hysterectomy.

Gynecologic Surgical Site Infections

Gynecologic procedures are performed by either the vaginal or the abdominal routes. The risk of infection depends in part on the approach. The vaginal route is a nonsterile approach, thereby increasing the risk of infection through contamination by vaginal flora. For example, vaginal flora may cause a cervical cuff infection after a vaginal hysterectomy. The abdominal route is a sterile approach that carries minimal postoperative wound infection risks similar to those for other clean abdominal surgical procedures. Another potential source of gynecologic healthcare-associated infections (HAIs) are devices that are introduced into the reproductive system. These devices may permit entry of microorganisms by direct contamination (from nonsterile equipment or the hands of healthcare personnel) or through indirect contamination via reservoirs associated with equipment, such as the dye used for a hysterosalpingogram.[27]

Approximately, 600,000 hysterectomies are performed annually in the United States, making the surgery the second most frequently performed surgical procedure for women of reproductive age (behind cesarean section) in the country. The rate of hysterectomy in the United States has decreased slightly from 5.4 per 1000 in 2000 to 5.1 per 1000 in 2004. Overall rates were highest among women 40 to 44 years of age and lowest among women 15 to 24 years of age. Geographically, the overall rate from 2000 through 2004 was highest for women living in the South (6.3 per 1000) and lowest for those in the Northeast (4.3 per 1000).[31]

Postoperative fever is observed in 15 to 33 percent of women undergoing a vaginal or abdominal hysterectomy. Two episodes of unexplained fever (less than 38°C, at least 4 hours apart, and more than 24 hours after surgery) may be due to pelvic or cuff cellulitis, pelvic abscess, or an infection that is remote from the operative site.[27]

Posthysterectomy infections usually arise from endogenous flora contaminating the surgical site or field. The National Nosocomial Infections Surveillance (NNIS) system defines postoperative wound infections as superficial, deep incisional, and organ/space.[32,33]The CDC includes statistics for hysterectomies in the NNIS system. The data for January 1992 through June 2002 indicates an infection incidence for abdominal hysterectomies of 1.4 per 100 operations with a risk index of 0; 2.34 per 100 operations with a risk index of 1; and 5.39 per 100 operations with a risk index of 2 or 3. The infection incidence for vaginal hysterectomies is 1.23 per 100 operations with a risk index of 0. The NNIS data for vaginal hysterectomies with a risk index greater than 0 are not available. Comparisons of hospitals' to NNIS rates must be done employing the same surveillance methodology.[33,34]

The length of hospital stay for all types of hysterectomies has decreased.[35]Therefore, many patients are discharged before manifestation of a postoperative wound infection, and postdischarge surveillance is necessary to identify these infections.

Perioperative antibiotic prophylaxis is recommended for hysterectomies to decrease the risk of postoperative wound infection. If a facility's surveillance data show that hysterectomy wound infections are of concern, compliance with antibiotic prophylaxis usage should be examined as a risk factor. The literature indicates that more than 70 percent of the patients studied received no antibiotic prophylaxis.[27]

Mention must also be made of other gynecologic procedures. Some procedures do not result in operative site exposure to flora in the lower genital tract. These include laparoscopy, ovarian cystectomy, and hysterosalpingography. Antibiotic prophylaxis is not recommended for laparoscopy or ovarian cystectomy. Data are not available on the benefit of antibiotic prophylaxis for ovarian cystectomy.[27]

The risks and prevention of procedure-specific infections are presented in Table 91-2. In addition to the risk of postoperative wound infections, it must be mentioned that pelvic gynecologic surgery, like other pelvic procedures, poses an increased risk of occupational exposure to bloodborne pathogens for healthcare personnel. Use of the new safety devices by operative personnel has been shown to prevent sharps injuries.[27]

Table 91-2 Procedure-Specific Infections: Risks and Prevention

Procedure	Risk(s)	Intervention(s) to Decrease Risk
Transabdominal procedures:performed by needle aspiration or incision through the abdominal wall (e.g., laparoscopy, hysterectomy, tubal and ovarian procedures).	Introduction of microorganisms into the wound or abdominal cavity with resultant peritonitis or incisional infection; laparoscopy has low risk of incisional infection; pelvic infection may occur in 0.1% to 0.3% of patients.	Use careful preoperative skin preparation; use prophylactic antibiotics as appropriate; sterilize laparoscopes before each use; if not feasible, use high-level disinfection.
Transvaginal procedures **Dilation and curettage (D&C)** **Intrauterine devices (IUDs)**	D&C has a risk of perforation of the uterus, endometritis, and tubal infections. An IUD acts as a foreign body; perforation of the uterus is possible; PID, tubal infections, and possibly peritonitis may occur.	Teach patient appropriate hygiene practices and to avoid tampon use for 2 to 6 weeks. Consider other (noninvasive) forms of birth control and avoid use in nulliparous females.

Vaginal hysterectomy	Vaginal hysterectomy associated with the risk of "cuff" infection; vaginal or intestinal microorganisms are most common.	Use general surgical interventions and use prophylactic antimicrobial agents as appropriate.
Diaphragm fitting	Transmission of STDs (e.g., HIV, HSV, HBV).	One study supported cleaning with soap and water followed by 15-minute soak in 70% alcohol; no data are available on efficacy of disinfectants against human papillomavirus because of inability to grow virus in vitro.
Cryosurgical procedure	Transmission of STDs and other organisms from contaminated probes.	Use cleaning followed by high-level disinfection of probes between patient use.
Transvaginal ultrasound	Transmission of STDs and other organisms from contaminated probes.	Cover probe with condom because condom may fail; most recommend cleaning and then using high-level disinfection of probe between each use. Ultrasound gel has been associated with cluster of infections; minimize potential for contamination of gel by keeping it in original container. Others have indicated alternative biocides that could be used for surface disinfection of the probe.
Abortion(includes removal or expulsion of products of conception before end of normal gestation period).	Use of poor aseptic technique or unsterilized instruments results in microbial contamination of endometrium; retained tissue can be a medium for bacterial growth.	Use aseptic technique; remove retained tissue promptly; instruct patient in hygiene practices.
Laser-assisted gynecologic procedure	The plume generated may contain viral DNA; may present a risk of exposure for the patient and operative personnel.	Evacuate plume through filter device; maintain good ventilation; consider use of high-filtration laser mask when laser is in use. SurePath should be considered superior to conventional tests used to detect low-grade and high-grade squamous intraepithelial lesions.**35**,**36**

From Rein MF. Volvovaginitis and Cervicitis. In: Mandell GL, Bennett JE, Dolin R, eds. *Principles and Practice of Infectious Disease,*6th ed. New York: Churchill Livingstone, 2005:1357–1371.

Gynecologic Procedures: Colposcopy

Colposcopy allows the cervix, vagina, and vulva to be examined through a binocular microscope. A 3 to 5 percent acetic acid solution is applied during colposcopy, and biopsies are obtained of all lesions that are suspected of being neoplastic. A colposcopy is considered satisfactory when the entire squamocolumnar junction and the margin of all visible lesions are visualized. Potential indications for colposcopy include the care of women with atypical squamous cells of undetermined significance, atypical squamous cells that cannot exclude high-grade SIL, atypical glandular cells, low-grade squamous intraepithelial lesions, or high-grade squamous intraepithelial lesions.[36]

As with other reusable medical devices, cleaning and disinfection of colposcopes is important to reduce the risk of HAIs. The manufacturer of the equipment used in colposcopy is responsible, under federal

regulation, to provide the user with cleaning and sterilization/high-level disinfection recommendations. The user is responsible for developing work practices based on the manufacturers' recommendations.

Conclusions

STDs carry serious health consequences for the public health and for those directly affected by these diseases. Some population groups in the United States are more vulnerable to STDs and the associated health and economic costs, including women and infants, adolescents and young adults, minorities, MSM, and people in corrections facilities.[1]Targeted STD prevention and treatment services can help identify infections among these populations, prevent complications, and reduce further transmission into the broader community.

Vaginal flora and medical devices are potential sources for HAIs linked with gynecological procedures. The risk of infections after gynecological procedures can be reduced through good infection prevention and proper cleaning and disinfection/sterilization of medical devices/instruments.

Future Trends

Future trends and research regarding STDs involve early and rapid identification, improved and more rapid contact investigations as shown through social network modeling, addressing increasing drug resistance, and enabling individuals across all socioeconomic groups to access the necessary healthcare and health education.

International Perspective

The impact of STDs and their resultant health consequences represent a global challenge. The effects upon populations and the social and cultural differences demonstrate the need for enhanced medical and social programs.

Abstract

Skin and soft tissue infections are common clinical problems that vary in type and severity. Breach of the skin from trauma, surgery, or primary skin disease is often a precursor to microbial penetration through the epidermis with a consequent range in progression from a superficial, self-limited infection to a life-threatening infection. If purulence at the site of infection is accessible for culture, procurement of a diagnostic test specimen will often provide clinically relevant, diagnostic information regarding microbial etiology, drug susceptibility, and potentially effective antibiotic therapy.

Key Concepts

- Anatomy of skin and subcutaneous tissues
- Pathophysiology of skin and soft tissue infections
- Microbiology of human skin and emergence of skin and soft tissue infections
- Clinical approach to the diagnosis of skin and soft tissue infections
- Common skin and soft tissue infections
- Infections associated with underlying conditions
- Cutaneous manifestations of systemic infections

- Necrotizing soft tissue infections
- Immunocompromised hosts: skin and soft tissue infections
- Management of skin and soft tissue infections due to drug-susceptible and multidrug-resistant pathogens

Background

Skin and soft tissue infections (SSTIs) comprise a wide variety of common clinical entities that range from mild abrasions to rapidly progressive, life-threatening necrotizing infections. Most skin infections are readily recognized and easily treated, but the more severe cases may initially appear benign, prompting a delay in diagnosis and treatment that may result in subsequent deep tissue infection with associated risks of morbidity and mortality. The purpose of this chapter is to provide a systematic classification of diagnoses and treatments of SSTIs, inclusive of surgical site infections (SSIs), for hospital epidemiologists and infection prevention specialists. SSIs are a major source of excess clinical and economic burden and several initiatives have targeted improvements in case identification, standardized reporting, and optimized quality of care for postsurgical patients at risk for infection.[1,2,3,4,5,6]Approaches to diagnosis and treatment of SSTIs should be guided by understanding of the type of infection and severity of the clinical presentation. Empiric treatment should include coverage of drug-resistant *Staphylococcus aureus*and drug-resistant Gram-negative bacilli, if such pathogens are suspected on the basis of local epidemiology, risk factors, or clinical features of the case presentation.[7,8]

Basic Principles

ANATOMY OF THE SKIN AND UNDERLYING SOFT TISSUES

*Epidermis.*Beginning at the skin surface, each successive layer of integument provides different mechanisms of immune protection. The outermost layer of the skin is the epidermis, a continually renewing stratified squamous epithelium and the major physical barrier of the skin. This protective layer can be invaded or bypassed by microbes through hair follicles and sebaceous glands. The basal layer of cells is the keratinocytes, which divide, differentiate, and eventually are sloughed from the skin surface.

*Dermis.*The dermis is separated from the epidermis by a basement membrane and from the deep fascia by an adipose-rich subcutaneous region. Collagen is a major dermal constituent that provides the pliability, elasticity, and tensile strength of the skin. Dermal collagen and elastin are embedded in a glycoprotein matrix, which provides a strong supportive skin structure. The interruption of dermal blood flow can restrict humoral and cellular host defenses against invading microorganisms and predispose to infection.

*Subcutaneous tissue and deep fascia.*The subcutaneous tissue layer is composed of fat cells, which serve as heat insulators, shock absorbers, and depots of caloric reserves. The superficial fascia separates the skin from underlying muscles and a deep fascial layer.

Skin And Soft Tissue Infections

PATHOPHYSIOLOGY OF SKIN AND SOFT TISSUE INFECTIONS

Skin integrity, bacterial colonization of the skin and the invasive potential of microbial pathogens, and the host's systemic defense mechanisms each contribute to host-microbe interactions associated with skin and soft tissue infection.

*Skin integrity and barrier functions of the skin.*SSTIs often arise from defects in the integrity of the epidermis associated with trauma, postoperative wounds, burns, or an underlying dermatosis. In certain circumstances, the portal of entry can be remote from the site of clinical infection, as evident in bacterial cellulitis of the lower extremity associated with tinea pedis and toe web intertrigo.[9]In some cases of cutaneous infection, the portal of entry cannot be identified. Focal skin infection may be the result of hematogenous seeding of the skin, as occurs in bacterial endocarditis or sepsis. Isolation of the etiological microorganism is often unsuccessful because of lack of purulence for diagnostic test specimen procurement, specimen transport and processing, or laboratory detection methods.

*Bacterial factors associated with normal skin flora and bacterial invasion of skin.*Normal skin flora is often colonized with *Corynebacterium*spp., *Propionibacterium acnes*, and coagulase-negative staphylococci. Commensal and pathogenic bacteria detected on the skin express proteases that influence host risks for SSTIs.[10]Proteases secreted by commensal bacteria contribute to homeostatic bacterial coexistence on skin, whereas proteases from pathogenic bacteria are used as virulence factors associated with breach of skin integrity.[10]Infection is initiated by microbial penetration of the epidermis to deeper tissue and cleavage planes where bacterial hyaluronidases break down host polysaccharides, fibrinolysins digest fibrin barriers, and lecithinases and lipases destroy skin cell membranes and adipocytes.[10,11]In addition, the local production of bacterial exotoxins by organisms such as *S. aureus*or group A streptococci may result in generalized inflammation such as staphylococcal scalded skin syndrome, toxic shock syndrome (TSS), or scarlet fever.[11]Some commensal and pathogenic bacteria are able to adhere to and colonize skin with altered integrity and within wounds. Initial bacterial adherence is due to hydrophobicity, ion exchange, and specific binding of bacterial adhesion molecules to cellular receptors. Staphylococci secrete polysaccharides that can form a biofilm together with multilayer cell clusters.[12]The highly structured communities within a biofilm are resistant to distinct immune effectors and have a decreased susceptibility to antibiotics in vivo.[12,13,14]Treatment that targets biofilm formation may improve wound healing and reduce wound infections.[14,14,15]

*Host systemic defense mechanisms.*Local blood circulation and host immune defenses are the primary determinants of the host response to invasive pathogens. The systemic clinical findings associated with SSTIs are often mediated by host cytokines. Lymphedema, chronic venous insufficiency, prior cellulitis, nephrotic syndrome, and diabetes mellitus are some of the recognized local and systemic predisposing factors to SSTIs. Infecting microbes may enter the lymphatic system, resulting in lymphangitis and regional lymphadenitis, or they may enter the circulatory system and cause bacteremia.

MICROBIOLOGICAL DIAGNOSIS

Historically, the etiological agents associated with SSTIs have been clinically predicted from the host presentation; diagnostic tests for the microbial etiology have had a relatively minor role in evaluation and management. The recent increase in prevalence of multidrug-resistant (MDR) bacterial pathogens in community and healthcare settings has augmented the benefit of specimen procurement for Gram stain and culture of purulent drainage, fluctuance, or tissue necrosis in SSTI cases.[16]The isolation of a single

pathogen is highly significant and can guide de-escalation of treatment after initial broad empiric antimicrobial coverage. Moreover, isolation of the causative organism may have epidemiological importance for surveillance and for infection prevention and control interventions recommended for patients with methicillin-resistant *S. aureus*(MRSA), vancomycin-resistant enterococci (VRE), and MDR Gram-negative bacilli.

EMERGENCE OF DRUG-RESISTANT PATHOGENS IN SKIN AND SOFT TISSUE INFECTIONS

Staphylococcal infections of skin and soft tissues are frequently encountered in community and healthcare settings. In recent years, community-acquired MRSA (CA-MRSA) infections have been reported in uncomplicated skin infections such as impetigo, secondarily infected open wounds, and more complicated SSTI such as cellulitis.[17,18,19,20,21,22,23]The most common microorganism isolated from hospitalized patients with SSTIs has been *S. aureus*, with a range in MRSA prevalence from as high as 23 percent in Western Europe to 47 percent in the United States.[18,19,20]Risk factors for MRSA infection among patients in healthcare settings include prior exposure to antimicrobial agents, prolonged hospital stay, stay in an intensive care or burn unit, proximity to patients colonized or infected with MRSA, use of invasive devices, surgical procedures, and underlying illness.[24]Methicillin resistance is defined as an oxacillin minimum inhibitory concentration (MIC) of at least 4 µg/mL, and such isolates are also resistant to other beta-lactams such as dicloxacillin and cefazolin.[19]Transmission dynamics for MRSA have been observed among healthy individuals, postpartum women, inmates within the criminal justice systems, and members of sports teams.[24,25,26,27]Modeling frameworks to further inform on the evolution and spread of MRSA suggest within-host and population-level competition between MSSA and MRSA strains.[28,29,30]

Strains of *S. aureus*with reduced susceptibility to vancomycin (VRSA) have been identified in France, Japan, and the United States.[31,32,33,34]Among seven cases of VRSA infection identified between 2002 and 2005 in the United States, all had a history of underlying chronic skin ulcers and either colonization or infection with MRSA and enterococci.[34]Although SSTIs due to VRSA remain rare, SSTIs due to CA-MRSA may be responsible for up to 50 visits per 1,000 patients, with more severe clinical presentations and higher SSTI recurrence rates among persons with CA-MRSA than persons with community-associated MSSA (CA-MSSA) SSTI.[35,35,36]

Colonization and infection with CA-MRSA can occur in individuals with no prior healthcare exposures, as well as in distinct patient groups whose common characteristic appears to be close person-to-person contact.[37,38,39,40]Thus, clinical and epidemiological risk factors in persons hospitalized for *S. aureus*infection cannot reliably distinguish between CA-MSSA and CA-MRSA. Treatment of complicated, purulent, and fluctuant SSIs involves incision and drainage in addition to oral or parenteral antibiotic therapy. Trimethoprim-sulfamethoxazole, clindamycin, doxycycline, and linezolid are often feasible treatment options.[41,42]With the increasing report of CA-MRSA SSTI, healthcare practitioners in outpatient and inpatient settings need to be familiar with prevention and treatment strategies for CA-MRSA.[41,42]

Enterococci are normal inhabitants of the gastrointestinal tract that are associated with SSTIs and invasive infections. In recent years, surveillance data suggest that both the percentage of *Enterococcus faecium*among enterococcal isolates and the proportion of vancomycin-resistant *E. faecium*(VREF) have significantly increased.[43]Judicious use of vancomycin is recommended to minimize the emergence of

vancomycin-resistant enterococcal (VRE) infections in both the community and in healthcare facilities. Results from randomized clinical trials of VRE in SSTIs report treatment response to quinupristin-dalfopristin, linezolid, and daptomycin.[44,45,46]

MDR Gram-negative microorganisms now account for a significant portion of complicated SSTIs.[47,48,49]

Risk factors for MDR Gram-negative infections include previous exposure to antimicrobial agents and recent healthcare encounters. The clinical presentations of MDR Gram-negative infections vary from benign to severe life-threatening infections such as necrotizing fasciitis. A high index of clinical suspicion is necessary for prompt case identification, isolation of the patient, and selection of appropriate antimicrobial therapy.

CLINICAL APPROACH

The patient's medical history and physical examination are key factors in the evaluation and management of SSTIs. The medical history should include a thorough review of comorbidities, recent trauma, environmental exposures, and recent antimicrobial exposure. One of the important early steps in evaluating patients with SSTIs is to determine if the lesion is discrete or diffuse, and if it is localized or spreading. There are four general clinical categories of SSTI: (1) discrete or localized skin lesions without toxicity; (2) discrete or localized skin lesions with toxicity; (3) diffuse or spreading infections in a normal host; and (4) diffuse or spreading lesions in an abnormal host. For patients with localized lesions, the absence of systemic toxicity (fever, chills, or malaise) implies that the infection has been restricted to the clinically evident site by effective host defenses. Such infections include impetigo, folliculitis, furuncles, carbuncles, and whitlow. In contrast, patients with discrete skin lesions associated with systemic toxicity must be considered to have disseminated SSTIs such as disseminated gonococcal infection, ecthyma gangrenosum, or other bacteremia, viremia, or fungemia. Spreading of erythematous skin lesions to involve the deeper structures of the dermis and the subcutaneous fat is typically referred to as cellulitis. When the infection extends even deeper into the adjacent fascia, it is usually classified as a necrotizing fasciitis. In a normal host with no recent epidemiologically significant exposures, the differential diagnosis includes erysipelas, streptococcal or staphylococcal cellulitis, streptococcal gangrene, and necrotizing fasciitis. If there is a history of recent relevant exposures, certain other infectious etiologies should be considered. Patients with evidence of SSTI with either fluctuance or necrotic tissue should have an expedited assessment for incision and drainage, surgical debridement, specimen procurement, and initial broad empiric therapy. Some host abnormalities are associated with a predisposition to particular types of SSTI that include polymicrobial foot infections in patients with diabetes mellitus and *Vibrio*spp. infections in patients with cirrhosis. Patients with conditions that lead to chronic edema are predisposed to cellulitis caused by streptococci and patients with iron overload are susceptible to *Listeria*spp., *Yersinia*spp., and *Vibrio vulnificus*infections.

COMMON SKIN INFECTIONS

*Impetigo.*Impetigo is a superficial skin infection occurring predominantly in children and persons of advanced age.[50,51,52]The skin lesion, or group of lesions, is typically characterized by erythema, or

blisters, without crusts that later progress to lesions that ooze and form yellow or honey-colored crusts surrounded by an erythematous margin. Bullous impetigo is generally associated with *S. aureus*infection, whereas nonbullous impetigo is usually associated with group A streptococcal infection. Bacteria isolated from bullous skin lesions have been shown in some subjects to contain the same strain of *S. aureus*as identified for nasal colonization, though the predictive value of screening for colonization in the outpatient setting remains inconclusive. Impetigo caused by group A streptococci is rarely associated

with systemic signs or symptoms, though glomerulonephritis is a recognized complication.[53] Untreated impetigo may slowly enlarge and involve new skin sites over several weeks. Epidemics of impetigo have been reported, most often in summer months.[54]

Folliculitis. Folliculitis is a circumscribed infectious process originating in hair follicles that can be classified as superficial or deep and by microbial etiology. Classically, this infection is caused by *S. aureus.* Less commonly, *Pseudomonas aeruginosa* folliculitis has been associated with water exposures. The initial lesions appear papulo-urticarial, usually within 48 hours of exposure, with evolution to pustular folliculitis. Treatment of superficial infections may be warm saline compresses and topical antimicrobial therapy, but infections that are more extensive often require oral or parenteral antimicrobial therapy.

Furuncles and carbuncles. A furuncle or boil is a focal erythematous skin infection complicating an antecedent folliculitis or developing as a deep nodule near a hair follicle. It almost never occurs on the palms or soles. A relatively thick dermis prevents spontaneous drainage to the surface and contributes to the hard, nodular, painful character of the lesion. Eventually, abscess formation occurs. The most common pathogen causing this type of skin infection is *S. aureus,* and treatment usually includes incision and drainage; warm moist compresses may be effective for smaller lesions. A carbuncle is larger than a furuncle, with infection spreading under and between fibrous septa in deep skin tissues, forming a series of interconnected small abscesses. Carbuncles usually occur at the nape of the neck or on the back or thighs, with drainage through clustered skin sites. *S. aureus* is the most common pathogen, and treatment is the same as for furuncles. The major problems associated with furuncles and carbuncles are the spread of infection and the risk for recurrence.

Erysipelas. Erysipelas is a painful, bright red, edematous, indurated skin plaque with an advancing raised border, sharply demarcated from the surrounding normal skin.[55,56,57] The most common sites of infection are the legs and face, often with previous cutaneous injury or congenital lymphatic disorders (e.g., lymphangiectasia). Group A streptococci is the most common microbial etiology, and the initial lesion spreads locally, and often rapidly, via the lymphatic system. Other less common pathogens are *Streptococcus* groups B, C, and G. Drainage is usually scant, and the organisms are not easily visualized via Gram stain or recovered in cultures. Two historical trials of erysipelas from the 1930s reported a nonantimicrobial treatment response to subjects randomized to receive ultraviolet light.[58,59] Today, mild erysipelas can usually be treated with oral antistreptococcal agents such as penicillin or clindamycin. For moderate to severe infections, parenteral therapy with penicillin is warranted. An enhanced response to therapy may be achieved by the addition of clindamycin to inhibit bacterial exotoxin production.[55] The duration of therapy is variable, but parenteral therapy may be required until resolution of the inflammation and fever, followed by a switch to oral therapy to complete a 2-week treatment course.

Cellulitis. Cellulitis has many of the features of erysipelas, but it often extends into subcutaneous tissues.[55,56,57] Cellulitis can be differentiated from erysipelas because it is not raised and is indistinctly demarcated from adjacent uninvolved skin. It is usually quite painful and tender, occurring most often on the legs, usually below the knee. In some cases, the overlying epidermis undergoes bullous formation or even focal necrosis resulting in epidermal sloughing and erosion; dermal and subcutaneous abscess formation rarely occurs. Red linear streaking and tender regional lymphadenopathy reflect efferent infection and lymphangitis. The most common microbial etiologies of cellulitis are *S. aureus* and *S. pyogenes,* though lymphangitis is typically associated with group A streptococcal infection.[60] Initial empiric

and subsequent treatment is usually by host factors, etiological agents, proximity of vital organs, and the need for hospitalization.[61,62,63,64,65,66]

*Paronychia.*Paronychia is infection of the proximal or lateral fingernail or toenail folds. The development of paronychia has been associated with repeated trauma or chronic moisture (e.g., dishwashing) to the hands or feet. Acute paronychia is most often due to *S. aureus*or group A streptococci via breach of skin integrity. In contrast, chronic paronychia is often caused by *Candida albicans*, and these chronic infections are common among individuals who have hands or feet in water for extended periods of time. Hence, minimizing water exposure is an important component of the treatment plan.

INFECTIONS RELATED TO UNDERLYING CONDITIONS

Secondary infections may develop in areas of preexisting damage, such as postoperative wounds, accidental trauma, bites, pressure ulcers, and neuropathic foot ulcers. The microbial etiology often reflects a preexisting condition and the resident microbial flora. These infections are usually localized, but they can sometimes result in deep tissue invasion with consequent risk for bacteremia and osteomyelitis.

*Surgical site infections.*The Centers for Disease Control and Prevention (CDC) has developed standardized definitions and surveillance criteria for SSI, and subsequent evaluations of such guidelines have been published.[67]In 2004–2005, a CDC initiative was undertaken to combine three national healthcare surveillance systems that focused on different populations and events to a single National Healthcare Safety Network (NHSN).[68]The SSI definitions were categorized into three nominal groups: superficial incisional SSI, deep incisional SSI, and organ/space infections. The superficial incisional SSI occurs within 30 days of the operative procedure and involves only skin and subcutaneous tissue in a patient with purulent drainage, a clinical isolate with organisms from an aseptically obtained culture, signs or symptoms of infection, or diagnosis by a surgeon or attending physician. Superficial incisional SSIs are further stratified as either superficial incisional primary (SIP) SSI in the primary incision of a patient who had an operation with one or more incisions or superficial incisional secondary (SIS) SSI in the secondary incision of a patient who had an operation with more than one incision.[68]Deep incisional SSIs occur within 30 or 90 days of the operative procedure, depending on the operative procedure as defined by NHSN, and involve deep soft tissues of the incision, and the patient has at least one specific sign or symptom of an SSI or a diagnosis of a deep SSI by a surgeon or attending physician.[69]These deep incisional SSI are also further stratified as deep incisional primary (DIP) SSI or deep incisional secondary (DIS) SSI. An organ/space SSI involves any part of the body, excluding the skin fascia or muscle layers, that is opened or manipulated during the operative procedure, occurs within 30 days of the operative procedure as defined by NHSN, and occurs in a patient with purulent drainage, aseptically recovered organisms, an abscess, or diagnosis of organ/space SSI by a surgeon or attending physician.[69]For decades, the most common bacterial pathogens isolated from SSI have been *S. aureus*, coagulase-negative staphylococci, *Enterococcus*spp., and *Escherichia coli*, followed by several less commonly occurring bacteria and *C. albicans*. More recently, empiric SSI treatment has become more challenging given the emergence of MDR pathogens, and the categorization of such makes geographic comparisons difficult.[70]

*Recurrent postsurgical cellulitis.*Recurrent cellulitis is commonly associated with postsurgical procedures such as venectomy for coronary artery bypass grafting, varicose vein stripping, radical mastectomy, and postradiation therapy with altered integrity of lymphatic drainage. Patients may experience acute onset

of pain, fever, and erythema at the site of a healed surgical scar. In healed donor vein site infections of the legs, tinea pedis may provide a portal of entry for infecting bacteria.[9] Although fungal pathogens are not usually isolated in this form of cellulitis, it is postulated that an underlying anatomic abnormality (e.g., impaired local lymphatic or venous drainage) predisposes to invasion with *Streptococcus* spp., *Staphylococcus* spp., or less commonly, other organisms. Cellulitis of this type often recurs with the same or similar anatomic distribution over several months or years. Acute episodes generally respond to standard empirical antimicrobial therapy for lower extremity cellulitis. Treatment of the predisposing tinea pedis, if present, should be part of the therapeutic strategy.

Postbite wound infections. Postbite infections occur after human, animal, and insect exposures.[71,72,73] Human bites are more prone to serious infectious complications than bites from animals. Clenched-fist injuries require that a physician experienced in hand surgery evaluates the wound to determine if the fascia is intact or if there has been deeper tissue penetration.[74] Bacterial infections after clenched-fist trauma are often polymicrobial, and the bacteriology includes *S. aureus, Moraxella* spp., β-lactamase-producing oral anaerobes such as *Prevotella* spp., and *Eikenella corrodens*.[74] Human bites are also a transmission source for bloodborne pathogens such as human immunodeficiency virus, Hepatitis B virus, and even syphilis.

Postbite infections from cats are more common (28 to 80 percent) than from dog bites (3 to 18 percent), with high risk for infection with *Pasteurella multocida* or *Pasteurella* species, often within 24 hours of the exposure.[71,72,73] Infection from aerobes (streptococci, staphylococci, *Moraxella* spp., *Corynebacterium* spp., and *Neisseria* spp.) and anaerobes (*Fusobacterium, Bacteroides, Porphyromonas*, and *Prevotella* spp.) has often been identified after cat and dog bites; *E. corrodens* has rarely been reported. Routine prophylactic antibiotics remain controversial, though empiric antibiotic therapy is most often recommended after human and animal bites with a combination regimen of β-lactam–β-lactamase inhibitor or ceftaroline.[73] Antibiotic prophylaxis has been recommended for bite wounds with full-thickness punctures, severe crush injuries, hand or foot sites, and sites with bone, joint, ligament, or tendon involvement. Prophylaxis is usually administered for a minimum of 3 to 5 days. Surgical management dictates that bite wounds be treated and left open, though facial lesions are often closed for cosmetic reasons. Complications of bite wounds to the hand include septic arthritis, tenosynovitis, and osteomyelitis. Healthy appearing dogs and cats should be quarantined for 10 days and sacrificed only if signs of rabies appear in the biting animal. Rabies prophylaxis regimens should be carefully considered.[75,76]

Of relevance, CA-MRSA has been identified in necrotizing fasciitis, which may initially mimic the appearance of a spider bite.[77] Some MRSA SSTI have been antecedent to spider bites, though in a study of more than 100 common household spiders, none were culture-positive for *S. aureus* or MRSA.[78]

Infections associated with trauma. The extent of the traumatic injury, environmental contamination (e.g., soil, standing water, sea water), and location of the injury are relevant in predicting the number and types of pathogens in the wound.[79] Infecting microorganisms can be derived from an exogenous source or the endogenous microflora (e.g., when intestinal perforation has been a consequence of the trauma). Most infections resulting from traumatic injury are associated with *S. aureus* or *Streptococcus* spp. Recent exposures may play a role in certain types of infection. For example, *Erysipelothrix rhusiopathiae* may cause cutaneous infections in anglers, butchers, and abattoir workers.[56] Puncture wounds of the foot,

from penetration of a nail or other sharp object through the sole of a shoe, require careful assessment, especially in diabetic patients.[80,81] Subsequent wounds are often infected with *P. aeruginosa*. *Vibrio vulnificus, Aeromonas hydrophilia, Plesiomonas shigelloides*, and *Chromobacterium* spp., especially after injuries associated with water immersion. Traumatic wounds contaminated with soil may be infected with *Clostridium* spp., *Pseudomonas* spp., or fungi.[79,82]

Pressure ulcers. Pressure ulcer infections are most commonly associated with immobility, advanced age, and inadequate nutrition, yet they can sometimes be associated with severe morbidity and sepsis. The most frequent anatomic areas are the sacrum, coccyx, greater trochanters, feet, elbows, and other pressure sites in bedbound individuals. Pressure ulcers in the sacrum, hip, and foot are particularly prone to colonization and secondary polymicrobial infection with fecal flora. In most cases these infections require combined medical and surgical care, with challenges related to chronic cutaneous wounds that are refractory to available advanced therapies.[83]

Diabetic foot infections. Foot infections are a significant cause of chronic osteomyelitis, limb loss, and sepsis in diabetic patients.[84] Neuropathy and angiopathy are the major pathophysiological factors contributing to infection in this group of patients. Although *S. aureus* or β-hemolytic streptococci usually cause initial diabetic foot infections, a mix of aerobic and anaerobic flora often causes secondarily infected foot wounds.[85] Superinfection has been attributed to Enterobacteriaceae, anaerobes (particular *Bacteroides fragilis* group), enterococci, and *P. aeruginosa*. Therapy is often complicated by physical factors such as patient immobility, diminished cutaneous sensation (neuropathy), and loss of subcutaneous soft tissue mass (padding over bony protuberances). Secondary bone infections (chronic osteomyelitis) are common, and, when present, require consideration of surgical debridement and long-term (6 or more weeks) antimicrobial therapy. Chronic foot ulcers are common problems in diabetic patients with neuropathy, and optimal glucose control is an important component of treatment response. Successful treatment may require debridement of devitalized tissue or callus, the design of physical padding or prostheses to prevent continued tissue trauma, or hyperbaric oxygen therapy.[86] Cooperative management between the internist and the orthopedic surgeon is highly desirable.

CUTANEOUS MANIFESTATIONS OF SYSTEMIC INFECTIONS

Skin lesions such as ecthyma gangrenosa, generalized erythroderma, purpura fulminans, and the characteristic appearance of cutaneous gangrene provide important clues to the diagnosis of life-threatening, tissue-destructive infections. Skin lesions often result from a preceding bacteremia (*Neisseriameningococcus, Staphylococcus*, or *Pseudomonas*), fungemia (*Candida* or *Cryptococcus*), systemic viral infection (varicella or measles), recurrent focal viral infection (herpes simplex or varicella zoster), or the rickettsioses (Rocky Mountain spotted fever and epidemic or endemic typhus). In many circumstances, the appearance of the skin lesions provides an important clue to the etiology of the systemic illness. Another cutaneous manifestation of a systemic infection is the rash caused by a bacterial exotoxin. Two microorganisms in this category are streptococci that elaborate the erythrogenic exotoxin responsible for scarlet fever and staphylococci that produce toxins associated with scalded skin syndrome and TSS.

NECROTIZING SOFT TISSUE INFECTIONS

This group of life-threatening infections may cause massive tissue damage, gangrene, profound systemic toxemia, and death. Rapid progressive destruction of cutaneous fat and subcutaneous fascia are the hallmarks of these infections, and the skin is often, but not uniformly, involved. A high index of

suspicion is necessary to make an early diagnosis of group A streptococcal necrotizing fasciitis, clostridial myonecrosis, Ludwig angina (face-neck), and Fournier gangrene (scrotum-perineum).[87,88] *P. aeruginosa* infection with sepsis and resultant ecthyma gangrenosum, and *Vibrio* infections may result in focal necrotic skin and soft tissue lesions.

Necrotizing fasciitis and necrotizing soft tissue infections. These infections are aggressive and involve fascia and adjacent soft tissues with a characteristic undermining of tissue planes. Patients with necrotizing fasciitis often have concurrent morbidities, such as diabetes mellitus, peripheral vascular disease, obesity, and malnutrition.[87,88] Prompt surgical exploration and debridement should be sought in all cases of rapidly evolving focal soft tissue inflammation and necrosis, and includes the opportunity to obtain tissue for Gram stain and culture.

Type 1 necrotizing fasciitis is a mixed infection caused by common aerobic and anaerobic bacteria.[87] Gas in the soft tissues is a classic feature of these infections and is particularly common in postoperative cases or patients with diabetes mellitus or peripheral vascular disease. Specimens commonly yield polymicrobial flora with pathogens such as *S. aureus, E. coli, Peptostreptococcus* spp., *Prevotella* spp., *Bacteroides* spp., microaerophilic streptococci, and *Clostridium* spp. Type 1 necrotizing fasciitis usually occurs at or near a surgical site (e.g., radical neck surgery) and has subacute onset within 4 days of surgery or a traumatic event. Some of these soft tissue infections may be referred to as "Meleney's synergistic gangrene" or, when the perineum and genitalia are involved, as "Fournier gangrene."[87]

Type 2 necrotizing fasciitis is caused by group A streptococci (*S. pyogenes*).[87] Gas is absent from soft tissues in type 2 necrotizing fasciitis, yet there is rapid clinical progression often associated with systemic signs suggestive of TSS. Streptococcal exotoxins (hemolysins, streptolysins O and S, and leukocidins) function as superantigens in the host and are thought to be responsible for many of the systemic features of this syndrome (hypotension, renal impairment, coagulopathy, and acute respiratory distress syndrome). Gangrene results after thrombosis of cutaneous and deep blood vessels and is often associated with focal intense pain. It may occur in otherwise healthy individuals and is characterized by sudden onset and widespread necrosis of fascia and deep subcutaneous tissues, sometimes with initial sparing of the skin and muscle.

Necrotizing fasciitis: Fournier gangrene. This is a distinctive form of type 1 necrotizing fasciitis typically affecting the male perineum and scrotum, with occasional extension to the abdominal wall or buttocks. In women, it can occur between the perineum and vagina. Predisposing factors include diabetes mellitus, alcohol abuse, local trauma, paraphimosis, periurethral extravasation of urine, perirectal or perianal infection, and pelvic surgery.[78] These infections begin abruptly with severe pain, and they may spread rapidly to the anterior abdominal wall or to the gluteal tissues. Cellulitis occurs near the portal of entry, and the involved area usually becomes progressively indurated and tender. As gangrene of the perineum develops, swelling and crepitation increase. Prompt surgical debridement and broad-spectrum, parenteral antibiotic therapy for polymicrobial infections with Gram-positive, Gram-negative, and anaerobic bacteria are indicated.

Necrotizing fasciitis: gas gangrene. Gas gangrene is usually induced by deep, penetrating trauma (e.g., gunshot or stab wound, crush injury). The wound causes compromise of the local blood supply and creates a relatively anaerobic tissue environment promoting the proliferation of *Clostridium perfringens* or related clostridial species. Clostridial soft tissue infection is usually heralded by intense and progressive pain at the affected site. Signs of systemic toxicity (e.g., fever, chills, tachycardia, shock) often follow.[89]

Gas in soft tissues (crepitus) may be detected by physical examination or imaging studies via computed tomography or magnetic resonance imaging. Radiographic imaging is less specific or sensitive than the detection of crepitus on physical examination, but imaging may be particularly helpful in identifying gas in deeper tissues.[89] Clostridial exotoxins are thought to play a major role in the development of systemic symptoms and local tissue necrosis. In clostridial cellulitis, gas is invariably found in the skin, but deep tissues may be spared. Initially, the overlying skin appears pale but eventually develops an orange discoloration followed by development of hemorrhagic or clear bullae. In addition, thin brown serosanguinous drainage may develop. Microscopic examination of the drainage reveals few, if any, white blood cells and many Gram-positive or Gram-variable boxcar-shaped bacilli (*C. perfringens*). Even in cellulitis, clostridial infections require both early surgical intervention and empirical antibiotic therapy.

SKIN/SOFT TISSUE INFECTIONS IN IMMUNOCOMPROMISED HOSTS

A wide variety of SSTI may occur in immunocompromised hosts and the pathogens identified in normal hosts are uncommon or occur with different clinical manifestations.[90,91,92] These organisms include mycobacteria, herpesviruses, *Nocardia* spp., *Cryptococcus neoformans, Histoplasma capsulatum, Coccidioides immitis, Toxoplasma gondii, Candida* spp., *Aspergillus* spp., *Pseudallescheria boydii, Sporothrix schenckii, Mucoromycotina* spp., and the enteroviruses. Despite the differential list of microbial etiologies, the clinical appearances of infected cutaneous lesions are often similar to those characterized in normal hosts. Many are the result of hematogenous spread occurring over several days, resulting in erythematous nodules or papules that are usually widely distributed and are minimally to moderately tender. Biopsy and culture of suspicious lesions are often necessary to make an etiologic diagnosis, because routine blood cultures are often negative (though lysis after centrifugation blood cultures are more sensitive and should be obtained). However, one should remember that the pathogens seen in normal hosts also occur in immunocompromised patients, and the degree of tissue inflammation and/or discomfort can be minimal.

TREATMENT OF SKIN AND SOFT TISSUE INFECTIONS

Four management principles are key to successful SSTI treatment outcomes.[93] These principles include (1) early diagnosis and differentiation of necrotizing versus nonnecrotizing SSTI, (2) early initiation of appropriate empiric broad-spectrum antimicrobial therapy with consideration of risk factors for specific pathogens and mandatory coverage for MRSA and MDR Gram-negative bacteria, (3) source control (i.e., early aggressive surgical intervention for drainage of abscesses and debridement of necrotizing soft tissue infections), and (4) pathogen identification followed by appropriate de-escalation of antimicrobial therapy. Initial management of complicated SSTIs should include collection of specimens for Gram stain, culture, and antimicrobial susceptibility testing from all patients who have abscesses or purulent lesions. Culture and susceptibility findings are useful for individual patient management and in regional surveillance for antimicrobial resistance. It has been documented that physicians and other healthcare personnel cannot accurately predict the pathogen associated with an SSTI.[93]

Empiric antibiotic therapy should be reviewed if and when susceptibility data are available. For MSSA, antistaphylococcal penicillin or a first-generation cephalosporin may be suitable. For CA-MRSA infections, trimethoprim and sulfamethoxazole (TMP-SMX), clindamycin, or tetracycline may be suitable. For healthcare-associated MRSA, vancomycin, linezolid, daptomycin, or rifampin plus fusidic acid may be suitable.[94,95] For CA-MRSA culture-positive wounds, in vitro susceptibility to TMP-SMX, tetracycline, erythromycin, clindamycin, and vancomycin should be assessed. If the isolate is resistant to erythromycin but susceptible to clindamycin, the clindamycin D-zone test should be performed if

clindamycin therapy is being considered. For HA-MRSA culture-positive wounds, an MDR phenotype and in vitro susceptibility to vancomycin, rifampin, and linezolid should be assessed.[94,95] Given the increasing prevalence of MDR pathogens reported for complicated SSTI, pathogen identification is of paramount importance.[70,93] All patients who have complicated SSTIs should have blood cultures obtained on admission and, if possible, before initiation of empiric antimicrobial therapy. In addition, cultures should be obtained directly from the incision and drainage of an abscess or intraoperative tissue when surgical debridement is performed.

FUTURE ANTIMICROBIAL DRUG RESEARCH AND DEVELOPMENT FOR SSTI

Future research and development programs that target antimicrobial treatment of SSTI will potentially enroll more severely ill subjects than in prior decades. In 2010, the U.S. Food and Drug Administration recommended that for randomized clinical trials of acute bacterial skin and skin structure infection, subjects with cellulitis, erysipelas, and wounds have a minimum surface area of 75 cm^2 (measured as a multiple of length by width), accompanied by lymph node enlargement or systemic symptoms such as fever greater than or equal to 38°C.[96]

INFECTION CONTROL FOR SKIN AND SOFT TISSUE INFECTIONS CAUSED BY MDR PATHOGENS

Contact Precautions are recommended by the CDC for hospitalized patients with SSI and SSTI caused by MRSA and MDR Gram-negative bacilli.[97] This guidance includes the use of a private room, wearing gloves on entering the room, wearing a gown if contact with the patient or items in the room is anticipated, and hand washing on removal of the gloves.[97] Despite the guideline, adherence to the guidelines has been suboptimal, and hand washing in particular is inadequate.[98] Topical mupirocin is effective in reducing nasal colonization of *S. aureus*, but the use of topical mupirocin to reduce the risk of surgical or nonsurgical infections caused by *S. aureus* has not been consistently high.[99,100] It also is not clear that topical mupirocin reduces MRSA colonization.[101] Attempts at combining topical mupirocin with antibacterial baths (e.g., in chlorhexidine or systemic agents) deserve further study.[102,103]

For SSI, recent evidence suggests that implementing surgical checklists, as created by the World Health Organization, was associated with reduction in mortality and morbidity.[104] Notably, the rates of SSIs were reduced in several medical centers from resource adequate and resource-limited settings.[103] Studies of silver-coated antimicrobial dressings, which help promote wound healing and inhibit biofilm formation, have been tested in various populations (e.g., burn wound, trauma wound, and to prevent SSI) and reveal promising outcomes.[105,106,107] Lastly, surveillance of SSI, especially after transfer from acute care to long-term care facilities is an important factor for accurate post-discharge SSI surveillance.

Conclusions

Healthcare professionals caring for patients with SSTI should practice strict compliance with the infection prevention practices and policies of the institution in which they practice. Hand hygiene, while easier to endorse than to enforce, is an essential component of patient and healthcare personnel safety. A high index of suspicion for the emergence of antimicrobial-resistant pathogens should be considered, and

contact isolation is a recommended component of the care of patients with drug-resistant pathogens. Antimicrobial stewardship is complicated by the limited specimen procurement and diagnostic armamentarium available for SSTI and infection prevention practitioners have a key role in the ongoing education of providers and patients.

Abstract

The genus Staphylococcus*comprises more than 40 validly described species, with the coagulase-positive species* Staphylococcus aureus*and the coagulase-negative species* S. epidermidis*and* S. haemolyticus*as the most common causes of healthcare-associated infections caused by staphylococci. Many staphylococcal species are both commensal microorganisms and pathogens. In particular,* S. aureus*is still one of the most feared pathogens, becoming increasingly virulent and resistant to antibiotic agents. This versatile pathogen harbors a wide array of virulence factors to enable colonization, invasion, aggression, and persistence processes. The study of slow-growing variant forms of* S. aureus*(i.e., the small-colony variants) has helped in the understanding of the persistent and recurrent infections. In the last decades, methicillin-resistant* S. aureus*strains have become endemic in hospitals worldwide, rendering almost all β-lactam antibiotics (penicillins, cephalosporins, and carbapenems) ineffective.*

Additionally, community-associated methicillin-resistant S. aureus*in persons without previous healthcare exposures as well as livestock-associated methicillin-resistant* S. aureus*have been increasingly reported. The majority of community-associated methicillin-resistant* S. aureus*strains have acquired Panton-Valentine leukocidin encoding genes, thereby greatly increasing their virulence. All these new strains and variants represent challenges for clinical microbiologists, infection preventionists, and epidemiologists.*

Key Concepts

• *Staphylococcus*species are generally divided into two groups: coagulase-positive staphylococci (*S. aureus*and some other of primarily veterinarian concern) and coagulase-negative staphylococci.

• *Staphylococcus*species are often part of the normal bacterial flora (microbiota).

• *Staphylococcus*species are common causes of healthcare-associated infections, including bacteremia, endocarditis, pneumonia, osteomyelitis, surgical site infections, skin and soft tissue infections, and device-associated infections. In addition, *S. aureus*can cause toxin-mediated diseases.

• Methicillin-resistant *S. aureus*is a frequent pathogen in healthcare-associated infections and has been shown to be associated with increased mortality in *S. aureus*bacteremia. Additionally, community-acquired and livestock-associated methicillin-resistant *S. aureus*have emerged.

• Resistance in staphylococcal species toward antibiotics of certain groups appears to be increasing.

• Hand hygiene and other precautions have been used successfully to prevent transmission and control outbreaks of *S. aureus*including methicillin-resistant *S. aureus*.

Background

The roots of modern infection prevention can be traced to the response to hospital outbreaks of staphylococcal infection in the 1950s and 1960s.[1]In the 1970s and early 1980s, attention focused on Gram-negative organisms as the most important healthcare-associated pathogens after Gram-positive infections were controlled. This, in turn, led to the development of many new antibacterial agents with potent activity against Gram-negative organisms (e.g., third-generation cephalosporins). In the 1990s, however, staphylococci again emerged as important healthcare-associated pathogens because of resistance to β-lactam antibiotics.[2]A most frightening development has been the spread of methicillin-resistance among *S. aureus*in the community, as these strains are attacking previously healthy young people (mean age, 14 years) with a devastating mortality rate (37 percent) in patients with necrotizing pneumonia.[3]Development of resistance in Gram-negative rods is an emerging threat; however, some progress in combating methicillin-resistant *S. aureus*(MRSA) has been achieved.

Basic Principles

The genus *Staphylococcus,*currently comprising 45 species and 21 subspecies, belongs to the family Staphylococcaceae of the order Bacillales (phylum Firmicutes) (Figure 93-1). They are Gram-positive, nonmotile, non-spore-forming cocci measuring 0.5 to 1.5 µm in diameter. They tend to form "clusters" in Gram stains of clinical specimens or cultures. This "clustering" helps to distinguish them from streptococci, which tend to form chains of cocci (Figure 93-2).

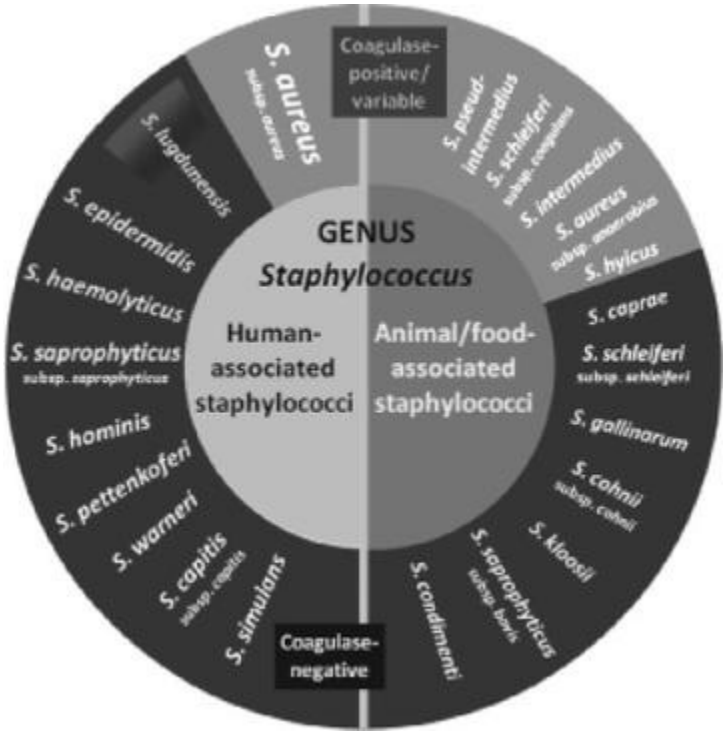

Figure 93-1.

The genus *Staphylococcus*. A selection of human-(left) and animal/food-associated (right). Coagulase-positive species are in the light grey area of the wheel. Coagulase-negative (sub-) species are in the dark grey area. Five species listed in the top left (*S. aureus*to*S. saprophyticus*) are the most medically important.*S. lugdunensis*holds a hybrid position as coagulase-negative species due to some clinical resemblances to *S. aureus*.

View Image

GROWTH CHARACTERISTICS

Staphylococci are normally catalase-positive. *S. aureus*grows rapidly under both aerobic (with oxygen) and anaerobic (without oxygen) conditions on blood agar and many other media.

*S. aureus*often grows as off-white or light-yellow to dark orange-yellow colonies, whereas the colonies of clinically relevant coagulase-negative staphylococci (CoNS) are mostly bright white. However, definitively differentiating between CoNS and *S. aureus*is only possible through the use of biochemical, immunological, and/or molecular methods. Individual colonies tend to be well defined, smooth, and hemolytic. Although the species name comes from the tendency of *S. aureus*to have a yellow pigmentation, this only occurs under certain growth conditions. For example, anaerobically grown or small colony variant (SCV) *S. aureus*fails to form pigment or hemolysins.

THE COAGULASE TEST

It is critical to be able to distinguish between *S. aureus*and CoNS.[4]Within the CoNS, the *S. epidermidis*group (*S. epidermidis S. haemolyticus*, *S. hominis,*and some other species) causes most CoNS infections in humans. It is therefore important to differentiate *S. lugdunensis* (resembling in some aspects *S. aureus*) and *S. saprophyticus*subsp. *saprophyticus*(causes

urinary tract infections). The most commonly used test is the coagulase tube test. *S. aureus*strains are coagulase-positive, whereas the other *Staphylococcus*spp. causing infections in humans are coagulase-negative. The coagulase-negative species *S. saprophyticus*is distinguished from other CoNS by its ability to ferment mannitol and by resistance to novobiocin. In contrast to many other CoNS, *S. lugdunensis*is clumping factor positive, as is *S. aureus*, and may cause severe infections.

Staphylococcus aureus

ANTIBIOTIC RESISTANCE

In the early 1940s, the first member of the β-lactam antibiotic family, penicillin, became available, and almost all staphylococci were highly susceptible. One decade later, 65 percent to 80 percent of healthcare-associated *S. aureus*isolates were reported to be resistant to penicillin. At present, many community and more than 90 percent of hospital-associated *S. aureus*isolates are resistant to penicillin. The mechanism causing this resistance in *S. aureus*and other staphylococcal species is the production of an enzyme, staphylococcal β-lactamase (penicillinase). This enzyme destroys the β-lactam ring of β-lactamase-sensitive narrow-spectrum penicillins (penicillin G and V) and susceptible broad-spectrum penicillins (e.g., ampicillin, amoxicillin, mezlocillin, and piperacillin).

Understanding the mechanism of this resistance led to the development of β-lactamase-resistant penicillins (methicillin, oxacillin, cloxacillin, dicloxacillin, flucloxacillin, and nafcillin) and first-generation cephalosporins (e.g., cephalothin and cefazolin). Penicillin-resistant *S. aureus*(PRSA) isolates that are methicillin-susceptible *S. aureus*(MSSA) are resistant to penicillinase-labile penicillins but remain susceptible to the penicillinase-stable penicillins (so-called antistaphylococcal penicillins), the β-lactam/β-lactamase inhibitor combinations, and the first- and

second-generation cephalosporins and carbapenems. The members of the large family of β-lactam antibiotics kill *S. aureus* cells by binding specifically to enzymes (transpeptidases) located in the staphylococcal cell wall. These transpeptidases are involved in the synthesis of cell wall peptidoglycan and are referred to as penicillin-binding proteins (PBPs).

Molecular Basis of Methicillin-resistant Staphylococcus aureus

MRSA, which can also be referred to as oxacillin-resistant *S. aureus* (ORSA), and strains of other methicillin-resistant staphylococcal species have acquired the *mecA* gene encoding an additional PBP, designated PBP2a (PBP2′).[5] PBP2a is characterized by low β-lactam affinity toward methicillin and penicillinase-labile penicillins. The *mecA* gene and its recently described homolog (*mecC*, originally described as *mecA*LGA251) are acquired on a mobile, foreign DNA element, the staphylococcal cassette chromosome *mec* (SCC*mec*) element. The SCC*mec* element occurs in several main types (10/2013: I– XI) and many subtypes.[6,7] The SCC*mec* types I and V encode exclusively for resistance to β-lactam antibiotics. Types II, III, and others determine multiresistance, as these cassettes contain additional drug resistance genes on transposons and integrated plasmids. Type XI contains a *mecA* homolog designated *mecC*.[8,9]

Borderline-resistant Staphylococcus aureus

Some penicillinase hyperproducers, the so-called borderline-resistant *S. aureus* (BORSA), mimic low-level resistance to methicillin even though they do not possess the *mecA* gene. For treatment purposes, this distinction can be important (see **25. Laboratory Testing and Diagnostics**).

Global Spread and Importance of Methicillin-resistant Staphylococcus Aureus

Methicillin became available in October 1960 for treating infections caused by β-lactamase-producing, penicillin-resistant *S. aureus*. However, within 6 months, strains resistant to methicillin were identified, first in England, then in other European countries.[10] Even though methicillin is no longer the agent of choice for treatment and susceptibility testing, the acronym MRSA continues to be used to describe *S. aureus* strains resistant to almost all β-lactam antibiotics (penicillins, cephalosporins, carbapenems) with the exception of the recently introduced anti-MRSA cephalosporins.

Starting at the end of the 1960s in Europe and Australia, epidemic multidrug-resistant MRSA clones (SCC*mec* types I–III, type IV subtypes) became a significant problem, which was followed closely by increased rates in the United States (recent U.S. MRSA rates ranging from approximately 30 percent to more than 50 percent) (Figure 93-3).[11,12] Except for some European countries with very stringent MRSA control precautions, MRSA rates have rapidly increased worldwide over the recent decades.[13,14,15,16] However, there are also signs of stabilization or even decrease in the incidence of MRSA infections in some regions (United States and several European countries such as France, Germany, and the United Kingdom).[17,18] MRSA has been found to be associated with increased morbidity, mortality, and hospital length of stay in *S. aureus* bacteremia and other entities.[19,20,21]

Figure 93-3.

Common risk factors	• Stays in hospitals, homes for the elderly, care homes • Chronic wounds • Catheters • Antibiotic treatment	• Close physical contacts with increased risk of abrasive skin injury (*e.g.*, team sports, recruit training) • Low socioeconomic conditions	• Direct contact with agricultural livestock (*e.g.*, farmers, veterinarians, abattoir employees)
Prevalent genotypes (U.S.)	• **ST 5 (*USA100, USA800*; t001, t002)** • ST8 (*USA500*; t064) • **ST36 (*USA200*; t018)** • ST45 (*USA600*; t004) • ST72 (*USA700*; t126)	• **ST 1 (*USA400*; t128, t558)** • **ST 8 (*USA300*; t008)** • ST30 (*USA1100*; t019) • ST59 (*USA1000*; t216, t316) • ST80 („European"; t044, t416)	• ST398 (t011, t034)
SCC*mec* types	• I, II, III, IV, VI, and VIII	• IVa, V, and VII	• IX, X, and XI (*mecC*)
PVL genes possession	• Rare	• Common	• Single cases
Antimicrobial susceptibility pattern	• Multiresistant	• Mostly no or only single additional resistances	• Tetracycline-resistant, seldom other resistances

Epidemiological MRSA types. Most common U.S. clonal lineages are given in bold; PFGE types (U.S. nomenclature) are given in italic; for *spa*types, the nomenclature according to the RidomSpaServer is used (**http://spa.ridom.de**, which is curated by **SeqNet.org**).

For *S. pseudintermedius*, an animal-associated (e.g., dogs, cats, horses) coagulase-positive staphylococcal species occasionally found in respective bite wounds, the acquisition of the *mecA*-encoded methicillin resistance has been also increasingly reported.[22]

Healthcare-associated Methicillin-resistant Staphylococcus aureus (HA-MRSA) *Strains*

Healthcare-associated MRSA (also designated as hospital-associated, or epidemic MRSA) strains are frequently resistant to many other classes of antibiotics, including macrolides (e.g., erythromycin), ketolides, lincosamides (e.g., clindamycin), tetracyclines, quinolones, and aminoglycosides (e.g., gentamicin), thus fulfilling the term "multidrug-resistant" (Figure 93-3). There is variable susceptibility to rifampin, fusidic acid, fosfomycin, trimethoprim-sulfamethoxazole, and other antibiotic compounds and disinfectants.

Community-associated Methicillin-resistant Staphylococcus aureus *(CA-MRSA) Strains: Emerging Issues in Patients without Risk for HA-MRSA*

An ongoing problem is the emergence of MRSA infections in patients with no apparent risk factors, including recent hospitalization. MRSA with unique genetic elements, designated CA-MRSA, are increasing in the United States and worldwide.[23]In the United States, the predominant clone is USA300 (ST-8), replacing the USA 400 (ST-1) clone most prominent before 2001 (Figure 93-3).[24,25,26,27]Meanwhile, the USA300 clone has emerged as the predominant cause of staphylococcal skin and soft tissue infections.[24]Outside of North America, a broader array of different CA-MRSA clones (besides ST-8, e.g., ST-5, ST-30 [Southwest Pacific clone], ST 59, ST-80 [European clone] ST-88, ST772 [Bengal Bay clone], and ST1797) is found.[26,28,29,30,31]

Most CA-MRSA strains carry genes encoding for the Panton-Valentine leukocidin (PVL), which is a bicomponent, pore-forming exotoxin with potent cytolytic and inflammatory activities.[32]PVL targets cells of the immune system, in particular human polymorphonuclear neutrophils.[3,33]

CA-MRSAs are associated with smaller SCC*mec*types (mostly subtype IVa, rarely types V and VII). Of interest, these types do not carry several typical resistance markers found in HA-MRSA, namely resistance to quinolone, clindamycin, and macrolides. However, multidrug-resistant CA-MRSA strains that have acquired multiresistant conjugative plasmids were also reported.[34]

Livestock-associated Methicillin-resistant Staphylococcus aureus *(LA-MRSA) Strains: Emerging Issue in Farming*

MRSA colonization and, less frequently, MRSA infections have been increasingly reported for many animal species.[35] MRSA clones found among companion animals such as dogs, cats, and small mammals are often show human molecular lineages indicating a transmission from human to pets. However, strains of MRSA that colonize livestock—in particular, pigs, cattle, and poultry—are caused by one specific clonal complex of MRSA (CC/ST398) that is distinct from human-derived strains (Figure 93-3).[36] LA-MRSA is regularly transmitted from colonized animals to farmers and other persons with close contact to agricultural livestock or their products. These individuals are the major source for the introduction of LA-MRSA into the healthcare setting.[37,38]

Compared to what is found in Europe, the presence of LA-MRSA in pigs (4.6 percent) and swine farm workers (20.9 percent) in the United States is lower.[39]

Vancomycin Resistance in Staphylococci

Since 1996, vancomycin-intermediate *S. aureus* (VISA) isolates have been identified first in Japan (Mu50 strain from a surgical wound infection that was refractory to vancomycin therapy) followed by further detections in the United States, Europe, and other regions.[40,41,42] Also in 1996, a Japanese group identified the first heterogeneous VISA (hVISA) strain (Mu3) with reduced susceptibility to vancomycin from a patient with MRSA pneumonia.[43] The hVISAs are interpreted as precursors to VISA. In 2002, a complete vancomycin-resistant *S. aureus* (VRSA) was identified from a temporary dialysis catheter-associated exit site infection of a Michigan resident. This was followed by several additional cases elsewherein the United States and in other parts of the world.[44,45,46]

The mechanism of VISA generation is thought to be caused in general by complex cell wall alterations resulting in cell wall reorganization and thickening in addition to reduced autolytic activity.[47,48,49] Because most VISAs are also resistant to the glycopeptide called teicoplanin, which is widely used outside of the United States, some authors prefer the acronym GISA (glycopeptide-intermediate *S. aureus*). Cases of true VRSA are still rare and are characterized by the acquisition of a glycopeptide resistance-encoding gene (*vanA*) originating from enterococci.

In the past decade, a phenomenon called "vancomycin MIC creep" was reported from some medical centers describing an overall population drift in clinical *S. aureus* isolates toward reduced vancomycin susceptibility but below the susceptibility breakpoint.[50,51] However, other studies noted no changes or even reductions in vancomycin MIC values.[52,53]

Clindamycin-inducible Resistance and the D Test

Erythromycin resistance in *S. aureus*is caused by the *erm*gene (erythromycin ribosome methylase), which confers resistance to the complete macrolide-lincosamide-streptogramin B antibiotic class, or by *msrA*causing macrolide and streptogramin (MLS_B) resistance.[54]In some erythromycin-resistant strains, inducible resistance to clindamycin may manifest when production of a methylase allows clindamycin resistance to be expressed. Standard susceptibility test methods do not recognize inducible MLS_Bresistance. Failure to identify inducible MLS_Bresistance may lead to clinical failure of clindamycin therapy. Conversely, labeling all erythromycin-resistant staphylococci as clindamycin resistant prevents the use of clindamycin (which is a useful therapeutic choice for skin and soft tissue infections, especially in penicillin-allergic patients) for infections caused by staphylococci in infections that are truly clindamycin-susceptible.[55]

There is a disk diffusion test called the D test, or D zone test, for detection of clindamycin-inducible resistance. In this test, the D-shaped zone of inhibition adjacent to a standard 15-µg erythromycin disk can identify *S. aureus*or CoNS strains with inducible resistance to clindamycin.[56]Clinical laboratories should have the capability to test staphylococci strains for clindamycin-inducible resistance in erythromycin-resistant isolates (Figure 93-4).

Other Antimicrobial Resistance in Staphylococci

Although still a rare phenomenon, some strains of *S. aureus*have developed resistance to more recently introduced alternative antibiotics with anti–*S. aureus*activity (including activity to MRSA). Although linezolid, the first oxazolidinone on the market, shows sustained potency and spectrum (less than 1.0 percent resistant strains),[57,58,59]resistance due to rRNA mutations has been detected in vitro and in the clinical setting.[60,61]The first linezolid-resistant MRSA was reported in 2001 from a patient treated with this agent for dialysis-associated peritonitis.[62]More alarming, a mobile, plasmid-borne linezolid resistance mechanism based on an RNA methyltransferase resistance gene (*cfr*) has emerged recently, but its incidence has remained low.[58,63]

Also, reports of treatment failures resulting from MRSA strains with reduced susceptibility or resistance to daptomycin, have been documented in the United States and Taiwan.[64,65,66,67] However, daptomycin still has excellent activity against MRSA.[68,69] The mechanism of resistance to daptomycin appears to be diverse, involving both cell membrane and cell wall events; the incidence of the development of spontaneous resistance appears to be very low.[70,71]

Tigecycline is the first drug approved in the class of glycylcyclines. Only a very few isolates (less than 0.5 percent) have so far been reported showing in vitro minimum inhibitory concentration (MIC) values around or above its threshold; however, this agent is still highly active against MRSA.[59,72,73] The mechanism of tigecycline resistance remains to be elucidated for staphylococci.

Currently, there are two available cephalosporins with MRSA activity—ceftaroline and ceftobiprole. Ceftaroline has been shown to be active against MRSA.[74,75] The same was reported for ceftobiprole, although this antimicrobial is under re-evaluation.[76,77]

LABORATORY IDENTIFICATION AND SUSCEPTIBILITY TESTING OF *STAPHYLOCOCCUS AUREUS*

Direct Examination by Gram Stain

Gram stain is an important testing technique but does not distinguish *S. aureus* from CoNS or other cocci occurring in clusters (e.g., "micrococci"). When testing sterile fluids (e.g., cerebrospinal fluid [CSF] and joint aspirates), Gram staining followed by direct microscopic examination may be helpful. For normally nonsterile fluids (e.g., respiratory secretions and swabs from wound surfaces), Gram staining is less appropriate for presumptive determination of *S. aureus*; however, the presence of inflammatory cells might support the impact of the microscopic findings.

Isolation, Identification, and Susceptibility Testing of Staphylococcus aureus

Columbia blood agar containing 5 percent defibrinated blood is the primary culture plate used for isolating *S. aureus* and CoNS from clinical specimens.[4] The recovery rate of *S. aureus* and other staphylococci can be significantly enhanced by the simultaneous use of an enrichment broth, which will be streaked after 24 and 48 hours of incubation on Columbia blood agar. For heavily contaminated sources such as feces, the use of selective agars for *S. aureus* such as mannitol salt agar might be helpful, but they have shown limited sensitivity and specificity. Current improvements in laboratory testing include the development of chromogenic solid agar media for *S. aureus* and/or MRSA detection. These media allow for more rapid presumptive determination. For all these agars, it is mandatory to confirm putative *S. aureus* isolates by biochemical,

molecular, and/or spectroscopic approaches. Classical methods include testing coagulase production, advanced third-generation latex agglutination assays for simultaneous detecting of protein A, clumping factor A, and the clinically most prevalent capsular polysaccharide serotypes 5 and 8, as well as biochemical procedures that are part of commercial manual and automated biochemical test systems. Targeting *S. aureus*-specific and universal genes followed by sequencing, respectively, allow highly specific identification of *S. aureus*by DNA amplification methods such as PCR. Most recently, matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF) mass spectrometry (MS) has been introduced as an alternative high-throughput approach for very rapid and specific identification of staphylococcal colonial material.[78]Of note, despite the molecular and MS developments for *S. aureus*detection and identification, cultivation of the pathogen is mandatory for subsequent further characterization of a given isolate for resistance testing and, if necessary, for determination of virulence factors or for genotyping purposes.

Antimicrobial susceptibility testing of *S. aureus*should be performed according to Clinical and Laboratory Standards Institute (CLSI) (**www.clsi.org**) or European Committee on Antimicrobial Susceptibility Testing (EUCAST) (**http://www.eucast.org**) reference methods.[79,80]Cefoxitin, a cephamycin antibiotic, which is a stronger inducer of the *mecA*regulatory system, has replaced oxacillin as a surrogate marker for testing methicillin resistance (*S. aureus*and *S. lugdunensis*, MIC ≥ 8 µg/mL). Of utmost importance is to distinguish MRSA from MSSA, which might be challenging due to the heteroresistance phenomenon of MRSA isolates (i.e., only a few bacterial cells of a suspension express β-lactam resistance in vitro). An alternative phenotypic method for fast and reliable verification of pure colonies suspicious for MRSA is the use of anti-PBP2a monoclonal antibodies supplied as a simple latex agglutination assay.[81,82]If the latex test is used for SCVs, then the number of colonies must be increased 100-fold.[83]The slow growth of MRSA SCVs makes disk diffusion and automated methods invalid.[84]

Since heterogeneous MRSA, SCV phenotype MRSA, and BORSA strains might be misdiagnosed by phenotypic methods for the detection and identification of MRSA, it has been strongly suggested to use a second method of identifying MRSA to verify the result for a given suspicious isolate.[83,85,86,87]

Screening for MRSA

Screening for MRSA has the specific purpose of detecting colonization in patients and, in outbreak situations, in medical personnel who have direct contact with colonized or infected patients. Thus, high-throughput approaches may be applied as chromogenic agars and/or bouillon media for cultivation and preliminary identification of MRSA, as well as polymerase chain reaction (PCR)-based techniques (see next section) for more rapid direct identification of MRSA carriers. Both approaches need a valid verification of species and oxacillin resistance in presumed MRSA isolates.

Molecular Genetic Methods of Identification

Molecular genetic methods that detect the presence of species-specific markers and resistance-indicating sequences were introduced starting in the early 1990s and have become important to

ensure correct identification of a given isolate as MRSA.[88,89]For the molecular identification of the species, in-house and commercial procedures have been described targeting either *S. aureus*-specific variable regions of universal genes (e.g., 16 and 23 rRNA genes, *rpoB*, *tuf*) or genes and gene fragments unique for *S. aureus*(e.g., *nuc*, *coa*, *clfA*, *femA*and *B*).[87,88,90,91,92,93]

The presence of the *mecA*gene or of its homologs (*mecC*) indicates the organism as methicillin-resistant, regardless of the strain or species of staphylococci. Of note, many currently available commercial tests do not target *mecC*.[94]In the case of discrepant results (phenotypic tests indicating MRSA versus negative molecular assay), the putative presence of a *mecA*homolog should be addressed (e.g., by applying respective in-house PCR strategies as published).[8,9,95]

Molecular methods are particularly important for characterizing MRSA of phenotypic variants (e.g., SCVs) and low-level heterogeneous MRSA.[83,87]

For molecular MRSA diagnostics, the sample (pure bacterial culture versus clinical specimens) as well as the intended purpose (MRSA screening versus detection of MRSA infection) has to be taken into consideration. Some available assays detect MRSA directly in certain clinical specimens (e.g., nasal specimen), whereas others require bacterial isolates from culture.

There are two general approaches to using rapid PCR-based MRSA screening from nasal swabs (and/or from other predilection sites, if approved), each with advantages and disadvantages. In the case of the so-called multiple-loci approach, the *mecA*gene plus an *S. aureus*-specific DNA sequence is targeted. In the presence of "contaminating" co-occurring methicillin-resistant CoNS from the physiological flora in parallel to MSSA, false-positive PCR results may occur.[96]The other approach, designated "single-locus amplification," overcomes this limitation by amplifying both a taxonomic and resistance marker in one step.[97]Here, the use of a surrogate marker (SCC*mec*region instead of *mecA*) may lead to false-positive or false-negative results (e.g., due to the exchange of the *mecA*gene by other genes, partial excision of the cassette ["drop out" isolates], and variability of the cassette primer binding sites).[98,99]Overall, all commercially available molecular amplification-based rapid MRSA screening assays are characterized by very good negative predictive values (approximately 97 to 99 percent) and hampered by moderate positive predictive values (approximately 65 to 95 percent).[100,101]

Given the limitations of both molecular strategies, *cultures remain essential*for confirming molecular results, for epidemiological purposes (genotyping), determination of the complete resistance profile (susceptibility testing), and, if necessary, the identification of further features (e.g., toxins). To achieve both rapidity and high predictive values, it is advantageous to use both PCR and cultures for MRSA screening.

Identification of Vancomycin (Glycopeptide)-intermediate Staphylococcus aureus*(VISA, GISA) and Vancomycin (Glycopeptide)-resistant* Staphylococcus aureus*(VRSA/GRSA)*

The detection of reduced susceptibility to vancomycin may be unreliable, and vancomycin nonsusceptibility is most likely underreported.[102,102]According to the CLSI recommendations,

isolates with MICs between 4 and 8 µg/mL are classified as VISA, whereas hVISA strains appear to be susceptible to vancomycin. VRSA strains (MICs of at least 16 µg/mL) can be reliably detected by the broth microdilution reference method.[103]To avoid reporting VISA isolates as "intermediate," the vancomycin MIC breakpoint has been refixed by the European Committee on Antimicrobial Susceptibility Testing (EUCAST) with more than 2 µg/mL as "resistant" for *S. aureus*(**http://www.srga.org/eucastwt/MICTAB/MICglycopeptides_v2.html**). Heteroresistance to daptomycin is rarely reported for hVISA/VISA isolates.[104]

Brain heart infusion (BHI) vancomycin (6 µg/mL) agar screen plate can be used to enhance the sensitivity of detecting VISA and VRSA isolates.[103]All isolates determined to have an elevated MIC for vancomycin (at least 4 µg/mL) using a MIC method that has not been validated for VISA/VRSA testing should be sent to a reference laboratory.[103]In particular, screening for hVISA requires labor-intensive additional testing (population analysis) to reveal its heterovariant phenotype.[105]The Centers for Disease Control and Prevention (CDC) website provides helpful information on VISA/VRSA (**http://www.srga.org/eucastwt/MICTAB/MICglycopeptides_v2.html**).

Diagnosis of Toxin-mediated Syndromes

In addition to clinical signs, the diagnosis of the staphylococcal toxic shock syndrome (TSS), caused mainly by the toxic shock syndrome toxin-1 (TSST-1), and the staphylococcal scalded skin syndrome (SSSS), caused by exfoliative toxins, is supported by the absence of protective antibody titers. Detection of isolates tested positive for the possession of genes encoding TSST-1 (or seldom staphylococcal enterotoxins [SEs] A and C) in TSS or for the possession of genes encoding exfoliative toxins (ETs) (classically ETA and ETB, newly described ETD) in SSSS may corroborate the diagnosis. Several PCR methods for classical toxin-encoding genes have been published and a few assays are commercially available.[106,107,108]PCR methods have been also reported to detect the genes of the more recently described nonclassical enterotoxins and enterotoxin-like pyrogenic toxin superantigens (PTSAgs), starting with SEG and reaching the letter U; however, their clinical impact is unclear.[109,110]

In cases of staphylococcal food poisoning, the staphylococcal enterotoxins (classically SEA –SEE) may be detected directly in food, vomit, or stool samples, which often harbor only the preformed heat-stable toxin. These antigen tests may not be readily available as a test of isolates in most hospital laboratories. Ultrasensitive immuno-PCR methods for toxin antigen detection may be available in research or reference laboratories.[111]

The detection of the CA-MRSA/MSSA associated PVL-encoding genes (*luk*S/F-PV) can be performed by in-house PCR or commercially available assays.[112]

TYPING METHODS TO IDENTIFY DIFFERENT METHICILLIN-RESISTANT *STAPHYLOCOCCUS AUREUS*STRAINS

During an MRSA outbreak situation, epidemiological investigations play an important role when used to differentiate clones of *S. aureus*(Figure 93-2). Identifying isolates with the same patterns from different patients suggests that the organisms originated from a single clone. Finding a unique clone in different patients who have a temporal or geographic relationship suggests transmission of the organism from patient to patient from a common source or mechanism.

Biotyping (chemical reactions) and antimicrobial susceptibility patterns can sometimes provide useful initial clues to strain identity. However, *S. aureus*may demonstrate very little variability in biotyping or susceptibility patterns, which makes these approaches less useful to differentiate among strains. As a result, other methods have been developed to distinguish one staphylococcal strain from another.[113,114,115]In the past, phage typing of *S. aureus*isolates was used to distinguish among strains in outbreak investigations. However, this technique is available only from reference laboratories because of expense, poor discriminating power, poor reproducibility, and complexity. Due to these limitations and difficulty in typing some MRSA strains, this method has been replaced by molecular typing approaches. Genotyping has now become an indispensable part of the hospital epidemiologist's armamentarium in investigating clusters of infections and outbreaks. If available, a molecular typing method should be used to investigate a cluster or an epidemic of *S. aureus*(particularly MRSA) infection. Molecular typing of chromosomal structures could also be supplemented by typing of the SCC*mec*element.

Pulsed-field Gel Electrophoresis

Analysis of chromosomal DNA restriction patterns by pulsed-field gel electrophoresis (PFGE) was a gold standard for years and the primary technique used for MRSA typing. PFGE is still used in many laboratories.[116]For PFGE, the isolates are cultured and embedded in agarose and lysed, then the isolate's DNA is digested with restriction endonucleases. Slices of the agarose containing the resultant "restricted DNA" are placed in wells of an agarose gel, where it is separated into individual fragment patterns under the influence of electric current. Usually, more than 14 fragments of DNA are resolved by this method and visible after ethidium bromide staining.

The fragment patterns of the tested isolates are compared to determine their relatedness. Depending on the fragment patterns, the isolates can be identified as follows:

• *Genetically indistinguishable*(the same fragment patterns)

• *Closely related*(two to three band differences resulting from a single genetic event such as point mutation, deletion, or insertion)

• *Possibly related*(four to six band differences resulting from two genetic events such as deletion, insertion, gain, or loss of restriction sites)

• *Unrelated*to the outbreak strain (seven or more differences resulting from three or more genetic events)[116]

This "fingerprint" method has the advantage of reproducibility and resolving power as a standard technique for epidemiologically typing of *S. aureus*. For the United States, a national database of

PFGE patterns defining originally eight lineages (USA100 through USA800) of pulsed-field types.[117] However, interlaboratory reproducibility and interpretation remain critical issues leading to replacement of time-consuming and expensive PFGE by sequence-based methods.[118] An example of a PFGE pattern from a LTC facility investigation is shown in Figure 93-5.[119]

Sequencing Methods

There are a couple of advantages to using sequence-based methods. One advantage is that sequencing data can be readily compared between different laboratories because of their portability. Another advantage is that these data are stored in expanding web-based databases, thereby producing a powerful resource for global epidemiology.[120] For *S. aureus*, the two main sequencing methods used are multilocus sequence typing (MLST) and typing of the polymorphic region X of protein A (*spa*typing) consisting of several numbers of variable 24 bp-repeats.[121,122,123] MLST sequences internal fragments of seven housekeeping gene loci, which are then used to characterize isolates resulting in allelic profiles or sequence types (STs). MLST may be less suitable for routine infection control due to high cost and labor intensity. Single-locus typing, particularly *spa*typing, is commonly used instead. This method has the advantage that only a single gene has to be sequenced and that its discriminatory power is comparable to PFGE and MLST typing analysis. Two nomenclatures (Harmsen [Ridom] and Koreen/Kreiswirth) for *spa*typing are in use.[122,124] An algorithm has been established that allows analysis of clonal relatedness of strains based on *spa*repeat regions.[125] Related STs and *spa*types, respectively, are grouped together as clonal complexes (CCs). The multiple-locus variable-number tandem-repeat assay (MLVA) is an alternative approach that has been shown to differentiate among strains that are indistinguishable by PFGE.[126]

PATHOGENESIS

*S. aureus*is an extraordinarily versatile organism that is able to produce a variety of proteins (enzymes, exotoxins, and adhesins) that are important virulence factors and are important for the pathogenesis of the different infections and toxin-mediated syndromes caused by this pathogen.

Virulence factors enable *S. aureus*and CoNS to colonize or invade human or animal hosts by adhering to host cells, tissues, and inserted devices.[127,128,129,130]Protein A, a bacterial surface protein adhesin of *S. aureus,*is able to bind to the tumor-necrosis factor α-receptor (TNF-R1), which has been shown to be abundant on airway epithelial cells. Binding of protein A to the TNF-α receptor elicits a TNF-α-like response, which leads to recruitment of neutrophils to the lung. Protein A also induces shedding of the receptor, which leads to binding of protein A and of TNF-α, thereby regulating protein A-induced recruitment of neutrophils.[131,132]Further details on adhesive mechanisms of staphylococci are given below (see the Coagulase-Negative Staphylococci section in this chapter).

Peptidoglycan, a polysaccharide polymer making up 50 percent of the bacterial cell wall, maintains cell wall integrity. Purified peptidoglycan can elicit many of the responses observed with endotoxin administration. Thus, it may be an important factor in producing the sepsis picture that is associated with severe *S. aureus*infection. Within the cell envelope, complex teichoic acid (TA) polymers are incorporated, which are either covalently linked to peptidoglycan (wall teichoic acid, WTA) or to the cytoplasmic membrane (lipoteichoic acid, LTA).[133]TAs are part of a group of phosphate-containing polymers that make up 40 percent of the cell wall by weight. Teichoic acids may be immunosuppressive and involved with adherence of *S. aureus*to mucosal surfaces and damaged tissues. Teichoic acids with higher amounts of D-alanine esters were associated with greater resistance to cationic antibiotics.[134]

*S. aureus*can produce extracellular polysaccharides (capsules) that enhance microbial virulence caused by interference with phagocytosis.[135]Most clinical strains belong to capsule group 5 or 8.[136]Capsule expression supports persistence of the bacteria in the bloodstream of the host and can promote abscess formation.[137]

*S. aureus*produces many enzymes, some of which have been implicated in the pathogenesis of infection. Catalase converts hydrogen peroxide to water and oxygen and may inhibit polymorphonuclear leukocytes (PMNs) from killing the ingested organism after phagocytosis. Coagulase (an enzyme used to distinguish between *S. aureus*and other staphylococci in laboratory testing) may contribute to pathogenesis. Hyaluronidase may be involved in the formulation of abscesses by enhancing the organism's ability to spread through tissues.

The pan-genome of *S. aureus*contains a huge variety of toxins, including pyrogenic toxin superantigens (PTSAgs), exfoliative toxins, and pore-forming toxins.[138]The staphylococcal PTSAgs comprise the toxic shock syndrome (TSS) toxin (TSST-1) and the staphylococcal enterotoxins and enterotoxin-like toxins, respectively (SEs/SEls). Staphylococcal enterotoxins A through E are the classical enterotoxins proven for superantigenicity and emetic capacity. Exfoliative toxins that circulate in blood during infection are responsible for the skin findings in staphylococcal scalded skin syndrome, which occurs in children. A pore-forming toxin called α-hemolysin (or α-toxin) lyses a broad range of host cells, including bacteria-destroying phagocytes, and it has been shown to play a significant role in *S. aureus*pneumonia.[139,140]*S.*

*aureus*also produces β- and γ-hemolysins, which may add to the pathogenicity of *S. aureus*, but they seem to be less potent virulence factors.

Clinical isolates of *S. aureus*are able to produce up to four bicomponent pore-forming toxins with the capacity to lyse cells of the immune system.[141,142]The pore-forming PVL kills human neutrophils by creating pores in the cell membrane.[33]PVL is carried by a phage and is carried by few of *S. aureus*strains (less than 5 percent). There is a strong association between this toxin and skin and soft tissue infections, but PVL has also been associated with severe necrotizing pneumonia.[3,112,143]This pneumonia is characterized by a sudden onset followed by rapid worsening of symptoms. Severe respiratory failure, and airway hemorrhages lead to high mortality.[144]Recently, clones of CA-MRSA strains that carry PVL have emerged worldwide.[145]The spread of these strains suggests that the combination, methicillin resistance plus PVL, confers a selective advantage to the strains. The arginine catabolic mobile element (ACME) carried by CA-MRSA strains (especially by USA300 strains) may be associated with virulence also. Elimination of ACME significantly reduced bacterial infectivity of target organs in a rabbit infection model and increased competitive fitness of the parent strain.[146]

*S. aureus*can sometimes act as an intracellular pathogen. Following internalization, *S. aureus*may adapt its metabolism to an intracellular lifestyle allowing long-term persistence within host cells.[147,148,149,150,151]These processes may lead to the generation of a special phenotype, SCV, which is of smaller size and has less pigmentation and less hemolysis, and can persist within the protected environment of the host cell.[84,152,153]SCVs are associated with persistent and recurrent infection, particularly from patients with chronic osteomyelitis, patients with device-related infections, patients with abscesses, and patients with both cystic fibrosis and chronic airway infection.[84,152,154,155,156]SCV strains are able to produce large quantities of proteases, which cause tissue damage to joints, and adhesins, which facilitate tissue attachment and uptake by host cells.[157,158]Of note, *S. aureus*SCVs retain the ability to revert to more rapidly growing organisms that produce larger quantities of toxins. In addition, the slow growth of *S. aureus*SCVs make them less responsive to cell wall-active antibiotics, and their decreased electron transport results in little aminoglycoside uptake because of reduced transmembrane potential, which is required for aminoglycoside uptake.[159]By persisting within the host cells, they are able to phenotypically resist antibiotics and escape host immune response.[160]

CLINICAL MANIFESTATIONS

*S. aureus*can cause suppurative infections of bone (osteomyelitis), soft tissue (abscesses and cellulitis), closed spaces (empyema), and heart valves (endocarditis). It also can release extracellular toxins that result in toxin-mediated syndromes. *S. aureus*infections may lead to overwhelming sepsis and shock in elderly persons (the most common cause of bacteremic death in people over 65 years of age). Any localized *S. aureus*infection can become invasive and lead to bacteremia. *S. aureus*is pre-eminent among bacteria in its ability to cause metastatic foci of infection once the bloodstream is invaded. Because of this characteristic, *S. aureus*infections

may require a prolonged course of intravenous antibiotics. Duration of treatment is determined by the site(s) of infection.

Skin and Soft Tissue Infections

Localized skin infections without a rash are common and are characterized by local abscess formation. These infections include folliculitis, furuncles, carbuncles, and impetigo. Many of the strains causing skin and soft tissue infections will carry PVL, and they may be resistant to methicillin. They are predominantly community-associated infections. *S. aureus*is the second-most common cause of cellulitis, whereas *Streptococcus pyogenes*is the most common. Both organisms must be considered when treating cellulitis, as organisms are difficult to recover by aspiration of the skin.

Disseminated Infections

*S. aureus*can also cause disseminated infection. After bloodstream invasion by *S. aureus*, various body sites are at risk for secondary infection. Examples of these secondary infections are vertebral osteomyelitis and septic arthritis. In both examples, *S. aureus*is the most common organism causing these types of infections. *S. aureus*is one of the most common organisms causing all types of healthcare-associated infections (HAIs).[161]A complication of bacteremia is the development of endocarditis. Although incidence of endocarditis related to *S. aureus*bacteremia declined over the years because of vigorous antibiotic intervention, it has re-emerged as the population has aged, as more intravascular devices are used, and as the organism has developed more resistant to antibiotic therapy.[162]

Toxin-mediated Complications

*S. aureus*is also the causative agent for classical toxin-mediated diseases. The PTSAgs (TSST-1 and SEs/SEIs) are the most potent activators of T lymphocytes, resulting in a massive release of proinflammatory cytokines and eventuating in shock, multiorgan failure, and death.[163,164]In addition, they have, for example, mitogenic activity and they are able to induce high fevers and stimulate neutrophil recruitment to a site of infection, resulting in local inflammation.

TSS caused mainly by TSST-1 (seldom by SEB or SEC) is characterized by fever, desquamative skin rash, low blood pressure, and multiple organ failure. It occurs in patients who are harboring toxin-producing *S. aureus.*TSS was originally described in menstruating women who were using hyperabsorbable tampons.[165]TSS has been subsequently observed in many other types of *S. aureus*infections, including postoperative wound infection.[166]

SEs cause the symptoms of foodborne illness.[164]When an enterotoxin-forming *S. aureus*strain contaminates food, and the food is inadequately refrigerated or undercooked, the organism proliferates and produces toxins. The toxins are relatively heat stable; therefore, incompletely reheated food can also cause food poisoning. The toxins are tasteless. Ingestion of food contaminated with toxin produces a sudden onset of nausea, vomiting, abdominal cramps, and diarrhea 2 to 6 hours after food ingestion, which typically subsides within 8 to 12 hours.

The phage-encoded exfoliative toxins (ETs)—also known as epidermolytic toxins—cause SSSS, also known as pemphigus neonatorum or Ritter disease. SSSS is typically found in infants.[167] This syndrome becomes evident with skin changes that look as if the child has suffered a burn with large blisters and reddened or sunburned skin.

EPIDEMIOLOGY AND TRANSMISSION

Epidemiology

*S. aureus*is often carried by humans as part of their physiological microbial flora. Forty to 50 percent of newborns are colonized shortly after birth (40 to 50 percent), but colonization can decrease with age depending on maternal carriage of *S. aureus*, breastfeeding, and number of siblings.[168]Persistent carriers (10 to 35 percent) may have one strain over prolonged time. Other carriers may harbor *S. aureus*intermittently.[169]*S. aureus*generally colonizes the anterior nares and the pharynx. From there, *S. aureus*can be transferred to skin and other body areas. The vaginal carriage rate in adult premenopausal women is about 10 percent, and bacterial counts increase at the time of menses (studies of vaginal carriage of *S. aureus*were initiated because of the occurrence of TSS in menstruating women in the late 1970s).[170]

Patients with diabetes who are receiving insulin, patients receiving long-term hemodialysis, and users of illicit intravenous drugs also have a higher carriage rate than the general population.[171,172,173]The higher carriage rate coupled with PMN deficiencies that interfere with killing of *S. aureus*leads to a higher incidence of *S. aureus*infection in these groups.

The CDC estimated that 65,269 cases of invasive MRSA infections (bloodstream infections, pneumonia, osteomyelitis, endocarditis, wounds, and cellulitis) occurred in the United States in 2011.[174]Of these, 16,560 cases (25 percent; 5.31/100,000 population year) were community-associated and 47,340 were healthcare-associated (75 percent; 20.06/100,000 population year). However, of all healthcare-associated cases, 34,876 (74 percent) were defined as infections with a community onset because the infection was detected from cultures taken in an outpatient setting or before the fourth calendar day of hospitalization. These patients also had risk factors such as history of hospitalization in the previous year. These data underscore the importance of MRSA as a source of community-acquired infections in the United States. A recent meta-analysis suggested that CA-MRSA infections began to appear in the United States in the early or middle 1980s, increased slowly through the 1990s, and began to rapidly emerge beginning in 2000. In the late 2000s a plateau was observed on a high incidence rate ranging between 84/100,000 people under Tricare-insured persons and 566 cases/100,000 people among Maryland veterans.[175]

Data from national U.S. surveillance systems on HAIs show that pathogen-specific pooled mean central line-associated bloodstream infection (CLABSI) incidence per 1,000 central line days decreased between 2002 and 2010 in intensive care units (ICUs) in the United States.[176]During this period, the CLABSI incidence density rate of *S. aureus*had fallen below those of *Candida*spp., *Enterococcus*spp., and Gram-negative rods—at least in adult ICUs. However, *S.*

*aureus*is still a predominant cause of ventilator-associated events (VAE) in the United States, which is underpinned by data from 31 U.S. community hospitals, where the top three causative pathogens were MRSA (24.5 percent), *Pseudomonas*spp. (14.0 percent), and *Klebsiella*spp. (11.9 percent).[177]Pooled data of 69,475 HAIs (CLABSI, catheter-associated urinary tract infections, VAE, and surgical site infections [SSIs]) that occurred from 2009 to 2010 show that staphylococci were the predominant pathogens detected, with *S. aureus*accounting for 16 percent and CoNS for 11 percent of all HAIs.[161]In this dataset, *S. aureus*was ranked as the most important bacterium to cause VAE and SSI, and CoNS were predominant among CLABSI. Of all *S. aureus*infections, 44 to 59 percent were MRSA, which reflects how endemic MRSA has become in the United States. This stands in contrast to European countries where, according to 2011 data from the European Antimicrobial Resistance Surveillance Network (EARS-Net), MRSA accounted for less than 5 percent of all *S. aureus*bloodstream infections in 8 of 30 countries, for less than 20 percent in 16 of 30 countries, and more than 40 percent in only 4 of 30 countries (**http://www.ecdc.europa.eu/en/activities/surveillance/EARS-Net**).

Transmission

Patients infected with MRSA or colonized asymptomatically are thought to represent the major sources for the introduction of MRSA in healthcare institutions.[178,179,180]MRSA is transmitted from patient to patient primarily via hand contacts of staff and care providers.[181,182]This mechanism of transmission emphasizes the need of rigorous hand hygiene; two studies have demonstrated that an increase of hand hygiene compliance (from 48 to 66 percent compliance and from 19 to 48 percent) resulted in a decrease of MRSA by 50 to 60 percent, respectively.[183,184]

Additionally, MRSA can be spread throughout the hospital environment, where it is able to survive on inanimate surfaces for at least 7 days and up to 7 months.[185,186]Hence, inanimate surfaces may also represent vectors for the transmission of MRSA in healthcare facilities, which underscores the importance of surface disinfection and cleaning.[187]

Colonized or infected healthcare personnel may also serve as a source or reservoir of MRSA, especially in outbreak situations.[188]Risk factors for acquiring MRSA during hospitalization vary and depend on the population studied and circumstances (endemic or epidemic). Important patient risk factors include prolonged hospitalization, antimicrobial therapy, stay in an ICU or burn unit, and exposure to a colonized or infected patient.[20,182]

The overall infection dose for MRSA is unknown. However, from in vitro data it can be presumed that less than 100 bacteria are sufficient, if inoculated in a wound.[189]In addition, many authors have estimated the "reproduction rate" for MRSA in healthcare settings (i.e., the number of secondary cases per index case due to transmission of the pathogen) ranging between 0.06 and 0.93.[190,191]Recently, a systematic review found that the daily transmission rate of MRSA was 1.37 to 140/1,000 patient-days, if Contact Precautions were not applied, and 0.81 to 9.0/1,000 patient-days if Contact Precautions were applied.[192]

Until recently, most MRSA infections were acquired in hospitals. But as early as 1993, the MRSA strains from healthy people who had not previously been exposed to the healthcare system were identified.[193]These CA-MRSAs have been predominantly isolated from children in day care centers, athletes, students, military recruits, man who have sex with men, jailed inmates, and homeless people.[34,194,195,196]

Hence, transmission of these strains occurs mainly where there is close physical contact between people.[197]The occurrence of CA-MRSA has also caused efforts to investigate the transmissibility of MRSA in households. It was found that, in case of an index case, MRSA transmission affected 47 percent of all household contacts.[198]Another study revealed that each MRSA index patient transmitted MRSA to one to four household members.[199]

Effective transmission of MRSA is also observed between animals and humans. This has been investigated predominantly on livestock farms. On European pig farms where MRSA CC398 is endemic, it was found that 77 to 86 percent of all farmers carry the same MRSA molecular strain as their animals.[200,201]Even after short-term exposure, intermittent MRSA CC398 carriage was detected. For the transmission of MRSA between companion animals and pet owners, there is limited data elucidating the frequency of transmission. In one study, it was found that, when sampling pets living in households of patients (n = 49) with MRSA infection, in 8 percent of the cases MRSA was detected in at least one companion animal.[202]

TREATMENT

Decolonization of Staphylococcus aureus *Carriage*

In the past two decades, there has been an emphasis on trying to eradicate MRSA colonization from the anterior nares and various other body sites to control epidemics. The impact of a nasal decolonization from *S. aureus*, whether the *S.aureus*is methicillin resistant or not, is a matter of recent debate. It has been assumed that colonizing strains may serve as endogenous reservoirs for overt clinical infections or may spread to other patients.[203,204,205]

Prospective studies showed that nasal carriage is a source of and risk for subsequent bacteremia and other infections caused by this pathogen.[203,206,207,208]Data suggest a benefit to the decolonized patient, especially if the patient has underlying diseases that may lead to hospitalization. This reasonable rationale is consistent with many studies showing reduced infections when nasal colonization is reduced prior to surgery and in hemodialysis patients.[209,210,211,212,213,214,215,216,217]The reason for debate is that recolonization and relapse occur frequently—mostly after discharge from a hospital. The success of mupirocin-based decolonization therapy was shown to be 94 percent 1 week after treatment and 65 percent 2 weeks thereafter.[208,218]However, a Cochrane database review demonstrated that the use of mupirocin ointment, though not necessarily leading to long-term eradication but enabling short-term decolonization in many cases, results in a statistically significant reduction in *S.*

*aureus*infections in patients nasally colonized with this pathogen.[219]Of note, strains can become resistant to mupirocin used for eradication.[220]

*Therapy for*Staphylococcus aureus *Infection*

In general, for annually updated and further information regarding the therapy of *S. aureus*infections, the current edition of *TheSanford Guide to Antimicrobial Therapy*[221]or other guidelines should be consulted. For skin and soft tissue infection, incision and drainage is the first treatment consideration. This is a prerequisite for the ultimate success of any antimicrobial regimen for cutaneous and subcutaneous abscesses or empyema.

The most active compounds for the therapy of staphylococcal infections in general are the members of the β-lactam class, with penicillin G as "number one" in activity followed by penicillinase-resistant penicillins and cephalosporins of the first and second generation. However, development of resistances (1) by β-lactamase leading to resistance to non-penicillinase-resistant β-lactams and (2) by acquisition of the SCC*mec*element leading to resistance to all β-lactams (with the exception of the novel cephalosporins with MRSA activity) limit their use currently.

Thus, the increasing threat caused by multidrug-resistant pathogens including MRSA has led to the development of several novel antibiotic (sub)classes, as well as compounds with substantial enhancements in the established antibiotic classes. Some compounds of these classes with anti-MRSA activity have already been introduced on the market (e.g., linezolid, daptomycin, tigecycline, ceftobiprole, ceftaroline).[222]Indications for these agents are based on noninferiority studies demonstrating that the novel compounds are as efficacious as the standard in the treatment of respective patients.[66,223,224,225]Although all these novel agents and those that are in the pipeline are welcome additions to the therapeutic armamentarium, further studies are highly warranted to investigate their complete clinical impact, their safety, and the development of resistance. In addition to novel compounds, a renewed interest in older agents with antistaphylococcal activity (e.g., fosfomycin, fusidic acid, rifampicin) is noted.

In the rare case of penicillin-susceptible *S. aureus*infection, penicillin G can be used effectively. However, since most *S. aureus*infections are caused by strains resistant to penicillin, the use of free or fixed combination with a β-lactamase inhibitor (clavulanic acid or tazobactam) or other β-lactamase-resistant agents is necessary. For MSSA that is penicillin-resistant, penicillinase-resistant penicillins such as nafcillin, oxacillin, cloxacillin, flucloxacillin, and dicloxacillin remain the most effective antibiotics, in particular for serious infections such as endocarditis or bone and joint infections. First-generation (e.g., cefalotin, cefazolin) cephalosporins are equally effective and potentially less toxic for the treatment of minor staphylococcal infections, such as skin and soft tissue infections.[226]In addition, they might be useful alternatives in patients with penicillin hypersensitivity or intolerance. Second-generation cephalosporins or cephamycins (e.g., cefuroxime, cefoxitin) are considered somewhat less effective than the first generations in covering *S. aureus*; however, they are sufficiently active against staphylococci. Cefepime, a fourth-generation cephalosporin, may also have sufficient activity against staphylococci. Carbapenems (e.g., imipenem, meropenem), as extremely broad-spectrum agents exhibiting also good activity against MSSA, should be held in reserve. For patients with penicillin allergy or

chronic renal failure, clindamycin or vancomycin is commonly prescribed. The use of vancomycin for severe MSSA infections is not advised, as it is inferior to the use of β-lactams in terms of mortality, bacteriological outcome, or relapsed infection.[227]For all antibiotic treatments of *S. aureus*infections that are intended to be performed by oral administration, it should be kept in mind that these antibiotics may have a low oral bioavailability (e.g., cefuroximaxetil and flucloxacillin). There is no evidence that *S. aureus*infections can be reliably treated with an antimicrobial drug against which resistance is expressed in vitro.[228]

MRSA represent a major therapeutic challenge due to the limited antimicrobial treatment options, in particular for severe, invasive infections, because appropriate substances are either less active than β-lactams against staphylococci or have problems in terms of toxicity and/or pharmacokinetic and pharmacodynamic parameters.[229]Traditionally, all β-lactam antibiotics are inadequate for therapy of MRSA. However, novel investigational anti-PBP2a β-lactams of the cephalosporin and carbapenem classes with increased PBP2a affinities and low MICs are being investigated.[230]The so-called anti-MRSA cephalosporins (ceftobiprole [recently withdrawn from the market] and ceftaroline) may be suitable options for empiric therapy of MRSA infections.[231,232,233,234]However, further clinical studies are needed to define their definite role in patient care.

Because healthcare-associated MRSA strains (and some reported community-associated MRSA strains) are multidrug-resistant, they are also frequently resistant to other antibiotic classes, such as macrolides, lincosamides, tetracyclines, and aminoglycosides. Therefore, glycopeptides (vancomycin preferentially over teicoplanin) and recently introduced novel antibiotics such as linezolid, daptomycin, and tigecycline, are the drugs of choice for MRSA infections.[66,235,236]

For severe MRSA infections except bacteremic pneumonia, vancomycin is still widely regarded as the drug of choice.[237]In an attempt to improve the bactericidal capacity in patients treated with vancomycin for severe staphylococcal infections (in particular, endocarditis), several combinations (aminoglycosides, rifampin, co-trimoxazole, fosfomycin, and fusidic acid) have been advocated.[238]However, they are still a matter of debate, and contradictory opinions are reported.[239]It has been suggested that using rifampicin with vancomycin improves outcome in uncomplicated bacteremia. Fusidic acid, fosfomycin, or aminoglycosides in combination with vancomycin may be relevant as an alternative to rifampicin. Unfortunately, there are only a few, partly uncorroborated studies available supporting combination therapy.[240]In the case of rifampicin, fusidic acid, and fosfomycin, resistance occurs rapidly; therefore, these compounds must always be administered in combination with another antibiotic.

Daptomycin, a cyclic lipopeptide, has an in vitro spectrum of activity exhibiting a concentration-dependent bactericidal activity for most clinically relevant Gram-positive bacteria, including MRSA.[241]Although daptomycin is not indicated for the treatment of pneumonia (because the drug is inactivated by surfactant), this agent is indicated for the treatment of complicated skin and soft tissue infections caused by MSSA or MRSA.[242,243]The U.S. Food and Drug Administration (FDA)

also approved the use of daptomycin for bacteremia caused by MRSA and right-sided endocarditis.[244]

Trimethoprim-sulfamethoxazole (SXT), a folate antagonist, may occasionally be useful in combination with rifampin.[238]When using SXT, one should keep in mind that *S. aureus*produces a very potent DNase that releases thymidine from DNA found in damaged host tissues and pus. As thymidine is known to reduce the activity of SXT, this agent should be used with caution.[245]

Quinolones (e.g., ciprofloxacin) are known to be become ineffective during treatment.[246]The newer quinolones (e.g., gatifloxacin, levofloxacin, moxifloxacin) have activity against Gram-positive organisms. Particularly due to the phenomenon of "collateral damage," a term that stands for the selection of drug-resistant organisms and the unwanted development of colonization or infection with multidrug-resistant organisms (MDROs), quinolones should not be used to treat staphylococcal infections.[247]

Tetracylines should be avoided for the therapy of *S. aureus*infections because their activity might be weak or not safe enough. Almost all LA-MRSA isolates exhibit resistance to tetracyclines.[38]

The minocycline derivate tigecycline, the first available glycylcycline, is a bacteriostatic agent with activity against a wide range of aerobic and anaerobic Gram-positive and Gram-negative microorganisms. This antibiotic is indicated for complicated skin and soft tissue infections (MSSA and MRSA) and complicated intra-abdominal infections (only MSSA).[242]

Clindamycin, a lincosamide, is widely used against *S. aureus,*particularly for skin and soft tissue infections based on the good tissue penetration. However, the inducible macrolide-lincosamide group B streptogramin (MLS_B) resistance may limit its use and clinical treatment failure has been observed.[248]

The first oxazolidinone available on the market, linezolid, is a narrow-spectrum anti-Gram-positive compound that is rather bacteriostatic (concentration-dependent) against staphylococci and shows very long postantibiotic effect against *S. aureus*.[249]It is approved in the United States for the treatment of healthcare-associated pneumonia and complicated skin and skin tissue infections, including diabetic foot infections caused by MSSA or MRSA. For MSSA, it is also indicated in the treatment of community-associated pneumonia and uncomplicated skin and soft tissue infections. For the treatment of MRSA pneumonia, vancomycin was the only available drug for many years. Unfortunately, the cure rates for *S. aureus*were disappointing, with mortality rates of almost 50 percent compared with 5 percent rates if the patients were treated with β-lactams.[250,251]An alternative therapeutic option for the treatment of MRSA pneumonia is linezolid, which has in contrast to vancomycin favorable lung pharmacokinetics and concentrations in the alveolar lining fluid that exceed the linezolid MIC for MRSA during the entire dose-to-dose interval.[252]Some studies reported clinical outcomes of study patients treated with linezolid to be significantly better than those treated with vancomycin therapy.[253,254]

However, this superiority has not been fully confirmed by other clinical studies including randomized clinical trials especially when considering mortality as the outcome parameter.[255,256]

Prevention and Risk Reduction

Ten to 35 percent of healthy adults are permanently colonized with *S. aureus*(primarily in the nose) and the others are at least intermittently colonized.[169]Therefore, *S. aureus*may be recovered from numerous body sites in both patients and medical personnel.[257,258]*S. aureus*is endemic to the healthcare environment and serves as a potential source for outbreaks. Because of the high incidence of endemic (background) *S. aureus*colonization and infection, outbreak identification is sometimes difficult. An outbreak is indicated by temporal and geographic clusters of *S. aureus*infection that exceed the baseline, especially in a special-care unit (e.g., ICUs and burn units) or in patients who rarely become infected (e.g., patients undergoing arthroscopy). Hence, outbreak control depends on careful epidemiological investigation to define what factors are important in causing infection among a population at risk. Standard epidemiological investigative techniques should be used, including defining a case, the population at risk, and the temporal sequence of the outbreak. Investigations are hampered if it is impossible to distinguish rapidly among strains. Consequently, molecular typing techniques are essential in the verification and characterization of an outbreak situation.

The management of MRSA could be perceived as a paradigm for preventing healthcare-associated transmission of multidrug-resistant microorganisms. Evidence-based guidelines to control and prevent MRSA colonization and infection have been established in many countries.[259]Examples of guidelines in the United States include those from the CDC and the Society for Healthcare Epidemiology of America (SHEA), and they are graded according to the evidence available from the literature.[260,261]Guidelines reflect the specific national epidemiological situation. For example, Dutch or Scandinavian guidelines reflect the low prevalence of MRSA in these countries. Given the low prevalence, it is possible for these countries to follow extensive eradication policies to contain MRSA—including case-tracing for single cases of MRSA colonization in the population, screening, strict single-room isolation in the healthcare setting, and decolonization of carriers after discharge from hospitals. In countries where MRSA is more disseminated (such as the United States) or where there are financial constraints, prevention of MRSA is usually restricted to more general principles, such as early MRSA detection (screening), the use of isolation precautions when caring for MRSA patients (gloves and gowns), and active decolonization. These measures are recommended by the majority of national guidelines. Recently, some investigators found that "shotgun" methods (i.e., performing decolonization therapies for all patients instead of only those identified by targeted screening) could be more effective in reducing the occurrence of HA MRSA.[262]Although this could represent an alternative in settings with "spillover" MRSA incidence, the various flaws identified for this specific study should be kept in mind.[263]Particularly, such an approach can facilitate the emergence of resistance against mupirocin beyond what has been observed already when this agent was widely used.[264]These effects could hamper MRSA prevention and control in the long run.

To ensure the proper implementation and consistent adherence to the prevention guidelines, educational programs for healthcare personnel should be conducted, assessed, and repeated as necessary.[265]

Since interinstitutional patient transfers play an important role transmission of healthcare-associated pathogens, hospitals are epidemiologically linked. Coordinated citywide or regional infection prevention and control policies and established healthcare networks can address this challenge and maintain patient safety throughout the continuum of care.[266,267]

Of note, some authors have recently described the effectiveness of several "bundles" that combine a series of preventive measures.[267,268]The evaluation of such bundles including their effectiveness, feasibility, and applicability to different healthcare settings and patients could guide future preventive efforts and tailor MRSA prevention measures to meet setting-specific needs. Overall, the major components (i.e., bundles) for *S. aureus*/MRSA prevention include the following: hand hygiene, Contact Precautions, surveillance, environmental cleaning, decolonization therapies, and antibiotic stewardship (see below).

Hand Hygiene

Failure to perform appropriate hand hygiene is generally considered to be the leading cause of MRSA spread. Consistent compliance with proper hand hygiene procedures is therefore a chief recommendation for the prevention of MRSA transmission.[260,269]The *Five Moments for Hand Hygiene*initiative developed by the World Health Organization recommends that staff disinfect their hands appropriately before and after all patient contacts, after contact with the patient's environment, after contact with potentially contaminated specimens, and before aseptic procedures. (**http://www.who.int/gpsc/tools/Five_moments/en/**). In addition, there needs to be adequate staff-to-patient ratios (especially in high-risk settings for transmissions, such as ICUs) that enable compliance with hand hygiene.

Contact Precautions

The use of Contact Precautions (such as gloves and gowns) is a tier one recommendation of the CDC/Healthcare Infection Control Practices Advisory Committee (HICPAC) MDRO guideline published in 2006.[261]See **29. Isolation Precautions (Transmission-based Precautions)**for more information about this important infection prevention aspect of MRSA prevention and risk reduction.

Surveillance

Surveillance for targeted MDROs is a hallmark of infection prevention and is a tier one recommendation of the CDC/HICPAC MDRO guideline published in 2006. Active surveillance for MRSA is a tier two recommendation of the CDC/HICPAC MDRO guideline published in 2006.[261]

See Figure 93-6 and **11. Surveillance**for more information about this important aspect of MRSA prevention and risk reduction.

Table 93-1

Tier 1.General Recommendations for Routine Prevention and Control of MDROs in Healthcare Settings	Tier 2.Recommendations for Intensified MDRO Control Efforts
Surveillance	Surveillance
• Use standardized laboratory methods follow published guidelines for determining antimicrobial susceptibilities of targeted and emerging MDROs.	• Calculate and analyze incidence rates of target MDROs (single isolates/patient; location-, service specific) *(IB)*
• Establish systems to ensure that clinical micro labs (in-house and outsourced) promptly notify infection control or a medical director/designee when a novel resistance pattern for that facility is detected. *(IB)*	• Increase frequency of compiling, monitoring antimicrobial susceptibility summary reports *(II)*
• In hospitals and LTCFs:	• Implement laboratory protocols for storing isolates of selected MDROs for molecular typing; perform typing if
• …develop and implement laboratory protocols for storing isolates of selected MDROs for molecular typing when needed to confirm transmission or delineate epidemiology of MDRO in facility. *(IB)*	• needed *(IB)*
• …establish laboratory-based systems to detect and communicate evidence of MDROs in clinical isolates *(IB)*	• Develop and implement protocols to obtain active surveillance cultures from patients in populations at risk. *(IB)*(See recommendations for appropriate body sites and culturing methods.)
• …prepare facility-specific antimicrobial susceptibility reports as recommended by CLSI; monitor reports for evidence of changing resistance that may indicate emergence or transmission of MDROs *(IA/IC)*	• Conduct culture surveys to assess efficacy of intensified MDRO control interventions.
• …develop and monitor special-care unit-specific antimicrobial susceptibility reports (e.g., ventilator dependent	• Conduct serial (e.g., weekly) unit specific point prevalence culture surveys of the target MDRO to determine if transmission has decreased or ceased. *(IB)*
• units, ICUs, oncology units). *(IB)*	• Repeat point-prevalence culture surveys at routine intervals and at time of patient discharge or transfer until transmission has ceased. *(IB)*
• …monitor trends in incidence of target MDROs in the facility over time to determine if MDRO rates are decreasing or if additional interventions are needed. *(IA)*	• If indicated by assessment of the MDRO problem, collect cultures to assess the colonization status of roommates and other patients with substantial exposure to patients with
	• known MDRO infection or colonization. *(IB)*
	• Obtain cultures from HCP for target MDROs when there is epidemiologic evidence implicating the staff member as a source of ongoing transmission. *(IB)]*

Environmental Cleaning

Cleaning and disinfection protocols can be instrumental in the control of possible environmental contamination with MRSA (see **107. Environmental Services**).

Decolonization Therapies

The evidence for performing therapies to decolonize patients with MRSA carriage is summarized above. The majority of studies have evaluated approaches using mupirocin nasal ointment alone or in combination with topical treatment of the skin and the pharynx.

Antibiotic Stewardship

Various studies have documented that the previous use of antibiotics is a risk factor for MRSA isolation among inpatients.[270,271] A recent meta-analysis has calculated that the relative risk of acquiring MRSA was 3-fold, 2.9-fold, 2.2-fold, and 1.9-fold increased for patients who had taken quinolones, glycopeptides, cephalosporins, and other β-lactam antibiotics, respectively.[272]

Moreover, interventions targeted on prudent antibiotic prescribing have been shown to be associated with a reduction of antimicrobial resistance among healthcare-associated bacterial pathogens.[273]

Coagulase-Negative Staphylococci

Currently, there are more than 30 identified species and subspecies of CoNS (Figure 93-1). The most important human pathogens, in terms of frequency and/or severity of illness, include *S. epidermidis*, *S. haemolyticus*, *S. saprophyticus* subsp. *saprophyticus*, and *S. lugdunensis,* followed by *S. capitis*, *S. hominis*, and *S. warneri*. Rare pathogens in human infections include *S. caprae*, *S. cohnii*, *S. pasteuri*, *S. pettenkoferi, S. schleiferi*, *S. xylosus,* and other species. Nowadays, laboratories should differentiate CoNS, because several approaches are available for this purpose, and automated identification systems often provide speciation with an accuracy of 70 to 90 percent.

ANTIBIOTIC RESISTANCE

CoNS isolates tend to be more resistant to antimicrobials than *S. aureus* isolates, though this gap is unfortunately closing. Similar to *S. aureus*, more than 90 percent of all *S. epidermidis* and *S. haemolyticus* isolates (community- or healthcare-associated) are resistant to penicillin because of production of β-lactamase.[274] The mechanism and expression of methicillin resistance in CoNS are similar to those in *S. aureus*. More than 80 percent of hospital-associated isolates are methicillin-resistant and, in addition, are also often multidrug-resistant.[73,275,276] In contrast to *S. aureus*, reduced or nonsusceptibility to glycopeptides is more common, usually heterogeneous, and (particularly for teicoplanin) is an emerging phenomenon.[277,278,279] In a recent UK study, 20.8 percent of all CoNS tested (*n*= 1214) were not susceptible to teicoplanin, but only one vancomycin-intermediate CoNS isolate was found.[280] In particular, *S. haemolyticus* shows unique predisposition among CoNS to acquire resistance to glycopeptides, often combined with methicillin resistance.[279,281] However, the vast majority of CoNS isolates are still susceptible to vancomycin, as reported from many studies.[68,73,276,282] Although the exact mechanism of staphylococcal glycopeptide resistance remains unknown, the basic mechanisms leading to reduced susceptibility to glycopeptides might be similar in both CoNS and *S. aureus*. Also for CoNS, cell wall thickening was reported.[283] Although rare to date, CoNS strains resistant to the recently introduced antimicrobials, including linezolid, daptomycin, and tigecycline, have been reported.[276,284,285]

A special form of CoNS "phenotypic" resistance has been demonstrated within biofilms produced by many different CoNS strains. The species- and strain-specific mechanisms of biofilm-associated CoNS antimicrobial resistance are likely multifactorial.[286,287] There have been mixed results from efforts to incorporate antimicrobial agents in medical devices to prevent CoNS colonization and biofilm formation; however, some of the newer agents offer some promise of penetration of biofilm to inhibit or kill adherent staphylococci[288,289] (see **70. Biofilms**).

EPIDEMIOLOGY

The capability of CoNS to cause infections is divergent. Medium-pathogenic staphylococci—including *S. epidermidis* group species, *S. lugdunensis,* and *S. saprophyticus* as typical members—could be separated from nonpathogenic staphylococci represented by species associated with (mostly fermented) food of plant and animal origin. CoNS species that are specific to animal species may occasionally colonize humans, although their isolation from various human clinical specimens has been described. Under defined conditions (immunodeficiency, implanted foreign bodies), these opportunistic pathogens may be found in human infections.

About a dozen CoNS species are well recognized as opportunistic pathogens and are able to cause clinically significant and rarely severe infections.[290] They are natural inhabitants of human skin and mucous membranes. *S. epidermidis* is the most prevalent species on human skin (65 to 90 percent of all staphylococci recovered), followed by *S. haemolyticus* and *S. hominis*. In addition, *S. saprophyticus* subsp. *saprophyticus* is a common cause of urinary tract infection in young women and is characterized by its capacity to adhere to uroepithelial cells.[291] *S. saprophyticus* urinary tract infections are almost all community acquired and peak in the spring.

Foreign body-related (FBR) infections (FBRIs), also called device-associated healthcare-associated infections (DA-HAIs), represent the most important clinical entity caused by CoNS. CoNS account for the majority of FBRIs, both of temporarily and permanently implanted devices.[292,293] The most common infection is associated with intravenous catheters; thus, they are a very common and increasing cause of healthcare-associated bacteremia.[161] From the U.S. nationwide SCOPE database, at the end of a 7-year period, the most common isolates recovered from healthcare-associated BSIs were CoNS (31 percent) followed by *S. aureus* (20 percent).[294] Patients with FBR-BSIs had significantly longer ICU and/or hospital lengths of stay, with higher mortality rate and hospital costs compared with uninfected patients.[295,296] In addition, CoNS infections are related to peritoneal dialysis catheters, CSF shunts, prosthetic valves, temporarily and permanently implanted devices, and vascular grafts.[297,298,299,300]

Almost all *S. epidermidis* infections are healthcare associated except for prosthetic valve infections, right-sided endocarditis of intravenous drug users, and some cases of peritoneal dialysis-associated catheter-associated peritonitis. Reservoirs of CoNS in the hospital setting have been difficult to identify. Until recently, it was believed that CoNS that cause infection come from the patient's indigenous flora. However, recent publications showed substantial evidence for strain transmission of CoNS among hospitalized patients. Applying molecular genotyping

methods, defined CoNS strains causing bacteremia were shown to persist in a neonatal ICU for one decade and could be recovered from the hands of personnel at the end of that period.[301]

Also for non-neonatal ICUs and wards, clonal spread of endemic, multidrug-resistant CoNS lineages has been shown.[302,303] In addition, outbreaks that are caused by cross-transmission have been reported.[304,305]

DIAGNOSIS

Gram stain of clinical specimens does not discriminate between *S. aureus* and CoNS. CoNS grow readily on many different media, but most commonly sheep blood agar is used (Figure 93-1).[4]

Routine identification of CoNS is classically performed in many laboratories using commercial test systems based on biochemical procedures that can differentiate between *S. aureus* and CoNS species mainly involved in human infections. Recently, CoNS identification by nucleic acid-based and mass spectroscopic methods supplements or replaces the classical diagnostic approaches.[4] Antimicrobial susceptibility testing of CoNS should be performed in general as noted for *S. aureus;* however, partially different breakpoints should be considered.[79,80]

Because CoNS colonize the mucosa and skin, a decision must be made for any given CoNS isolate from a clinical specimen about whether it represents a true infection, colonization, or a contamination at the time cultures were obtained. This is especially true when evaluating cultures related to skin and soft tissue infections, surgical site infections, and positive blood cultures.[306] Precisely, because CoNS are an important cause of healthcare-associated BSIs, interpretation of cultures growing CoNS should be done based on knowledge of the usual types of infections caused by this organism, clinical and microbiological findings, and their pathogenesis.[307]

Although CoNS are the most common organisms isolated in blood cultures, a large proportion of these isolates represent events of contamination rather than true bacteremia.[308] The difficulty, however, is trying to make the correct categorization, especially when CoNS are detected in blood cultures from patients in ICUs, who are often febrile and have one or more intravascular catheters or other devices in place. Several indicators can be used to identify true CoNS bacteremia, including occurrence of multiple positive blood culture sets, growth in both aerobic and anaerobic bottles, detection of positive blood cultures less than 48 hours after cultures are obtained, and presence of foreign bodies in the patient, which predispose to CoNS infection (especially intravascular catheters that are left in place for more than 3 days).[309,310] However, in the presence of signs of sepsis, a single blood culture positive for CoNS may be significant.[311]

For isolates of non–*S. epidermidis* CoNS, the finding of methicillin resistance may be associated with true bacteremia. Conversely, hints that CoNS isolated from blood cultures may be contaminants include the finding that only the aerobic bottle of a set is positive; having two or more sets of blood cultures with only one or a minority of bottles being positive; the finding in a patient who does not have a foreign body in place (especially useful in patients who have blood cultures done on admission to the hospital); delayed growth (more than 48 hours) of a positive blood culture, indicating small numbers of organisms in the initial specimen (i.e., skin

contamination); and more than one strain (usually detected by differences in antibiograms or colony morphologic appearance) of CoNS isolated in positive cultures.[309]Clinical and laboratory models have been developed to rapidly classify blood cultures in terms of contaminants or true-positive cultures using both clinical and laboratory data.[312,313]However, no generally accepted gold standard exists for differentiating pathogenic CoNS from contaminants.

CLINICAL MANIFESTATIONS

Unlike *S. aureus*, which causes acute, pyogenic infections, infections caused by CoNS tend to be more gradual in onset and less severe overall. The exception is *S. lugdunensis*(discussed later in the chapter). The increasing use of indwelling or implanted foreign bodies has become essential in modern clinical practice but is associated with the possibility of infectious complications. Signs and symptoms that suggest catheter-associated infection, such as purulent drainage from the exit site or skin erythema, are usually absent despite a positive semiquantitative catheter culture that implicates the catheter as the source of the bacteremia. CoNS, in particular *S. epidermidis*, are the most common organisms that cause infections in CSF shunts.[300,314]Infections usually occur close in time to placement, revision, or other manipulation of the shunt. Additionally, *S. epidermidis*(followed by *S. haemolyticus*) is the most common organism isolated from patients with peritonitis associated with peritoneal dialysis.[315] Peritonitis is usually manifested by abdominal pain and development of cloudy peritoneal fluid. Furthermore, chronic, polymer-associated clinical syndromes may also be at least in part associated with *S. epidermidis*. These syndromes include the aseptic loosening of joint prostheses due to infections of prosthetic joints, postoperative late-onset endophthalmitis after implantation of artificial intraocular lenses, and fibrous and capsular contracture syndrome after mammary augmentation with silicone prostheses.[316,317,318]A characteristic of these infections is that they develop slowly and may have only minimal signs and symptoms.

Although increasingly reported, CoNS are still a rather uncommon cause of native valve endocarditis. However, they are the most common cause of prosthetic valve endocarditis (approximately 40 percent of all cases) and of vascular graft infections.[319,320,321,322]Many of the cases of *S. epidermidis*prosthetic valve endocarditis that occur within the first year postoperatively are caused by inoculation of the organism at the time of surgery, especially cases that become clinically apparent within the first 2 months after surgery. Although clinical courses of CoNS-caused prosthetic valve endocarditis, they have been traditionally described as subacute or chronic without fulminant signs of infection. More aggressive presentations have recently been acknowledged.[323,324,325]

In contrast to healthy, term infants where CoNS habitually represent commensals, preterm newborns are specifically predisposed to invasive CoNS infections because of they are immunologically immature and have impaired skin and mucosal barriers. Thus, CoNS septicemia of preterm infants has been recognized as one of the major types of late-onset neonatal infection.[326,327,328,329]*S. lugdunensis*, a skin commensal preferentially of the lower parts of the human body, has a specific position among CoNS rather resembling *S. aureus*in many aspects. This species is an emerging pathogen that is being more frequently recovered from patients;

however, it is infrequently detected compared with *S. aureus*and *S. epidermidis*. *S. lugdunensis*is known to cause aggressive and destructive courses of endocarditis with high mortality unusually fulminant for a CoNS species.[330,331]*S. lugdunensis*bacteremia is associated with endocarditis at an extremely high percentage (up to 50 percent).[332]It has been implicated also in other invasive diseases, such as soft tissue abscesses, septic arthritis, peritonitis, meningitis, and foreign body-associated infections.[333,334,335]Although virulence factors remain largely unknown, some studies suggest that the organism has the ability to form biofilms on host tissues or prosthetic surfaces and interact with host cells. The formation of small-colony and other phenotypic variants was described in a case of recurrent pacemaker-associated BSI.[336]

PATHOGENESIS

In the case of foreign body-associated infections, the host defense mechanisms often seem to be unable to handle the infection and, in particular, to eliminate the microorganisms from the infected polymer device. In addition, antibiotic therapy is frequently unable to interrupt this kind of infection despite the appropriate application of antibiotics with proved *in vitro*activity. The pathogenesis of foreign body-associated infections caused by *S. epidermidis*is characterized by colonization of the polymer surface through the formation of a thick, multilayered biofilm (Figure 93-1).[337]Biofilm formation proceeds in two stages, comprising (1) a rapid attachment of the staphylococci to the surface of the implanted device followed by (2) a more prolonged accumulation phase that involves cell proliferation and intercellular adhesion.[288]Finally, staphylococcal cells may disaggregate from the macrocolony on the polymer surface and drift into the bloodstream, resulting in metastatic and embolic complications.

To initiate invasive infections, staphylococcal cells must adhere to the extracellular matrix (ECM) or cells of the host tissue. This multifactorial process is very complex and essentially mediated by adhesins, which are staphylococcal proteins undergoing strong interactions with host structures. The group of proteinaceous surface-associated adhesins can be divided into two groups. The first group comprises proteins that are covalently bound to the bacterial cell wall (microbial surface components recognizing adhesive matrix molecules, MSCRAMMs). The second group comprises noncovalently linked proteins that are secreted but rebind to the bacterial cell surface—these include the secretable expanded repertoire adhesive molecules (SERAMs; so far only in *S. aureus*), bifunctional autolysin/adhesins, and membrane-spanning proteins (e.g., Embp in *S. epidermidis*).[338]MSCRAMMS of CoNS comprise the accumulation-associated protein Aap, the biofilm-associated protein (Bap)-homologous protein (Bhp), and the clumping factor (Clf).[339]Bifunctional autolysins have been demonstrated for *S. epidermidis*(AtlE), *S. saprophyticus*(Aas), *S. lugdunensis,*and some other CoNS species.[340,341,342]Of the group of nonproteinaceous staphylococcal adhesins, a specific polysaccharide antigen termed "polysaccharide intercellular adhesin" (PIA) encoded by the *icaADBC*operon has been shown to be involved in intercellular adhesion and biofilm accumulation.[343,344,345]Also, other factors such as the accumulation-associated protein (AAP) seem to be involved in accumulation and biofilm

formation, as well.[339]Furthermore, the cell wall teichoic acid covalently linked to the peptidoglycan is implicated in adherence processes of *S. epidermidis*.[346]

*S. lugdunensis*and the subspecies of *S. schleiferi*resemble *S. aureus*in that these species may express a clumping factor and/or produce a thermostable DNase and coagulase, respectively. Clinical isolates of *S. lugdunensis*may produce extracellular slime or glycocalyx, which has a role in bacterial colonization and interferes with the phagocytosis-associated activities of neutrophils.[347]Esterases, proteases, lipases, and other enzymes that may act as invasion factors have also been detected in this species.[286]A few reports are available on the interaction of *S. lugdunensis*with components of the ECM and host tissues and the presence of MSCRAMMs.[348]

*S. saprophyticus*subsp. *saprophyticus*shows a greater capacity to adhere specifically to uroepithelial cells compared with other CoNS. A surface-exposed 160-kDa protein with hemagglutinin/adhesin properties mediates the specific binding to uroepithelial cells.[349]Further proteins, such as the *S. saprophyticus*surface-associated protein (Ssp) and a serine-aspartate repeat protein (Sdrl), also may be involved in the interaction with the uroepithelium.[350,351]

TREATMENT

Since the majority of clinical CoNS strains are methicillin resistant, most infections by CoNS require treatment with glycopeptides (e.g., vancomycin). In addition, teicoplanin has potential for use as an alternative in the treatment of infections caused by CoNS. However, in general, it exhibits higher MICs than vancomycin in CoNS. It must be pointed out that glycopeptides are poorly bactericidal against staphylococci. The newly marketed agents, including linezolid, tigecycline, daptomycin, and ceftaroline, show excellent activity against CoNS.[58,74,276,352]If an isolate is methicillin susceptible, replacement of vancomycin by β-lactamase-resistant penicillins is advisable. Simultaneous use of antibiotics of the cell-wall active class (including vancomycin) and rifampin act synergistically to treat infections with CoNS. However, combination of antibiotics is not generally recommended for catheter-associated BSIs caused by CoNS.[353]

As the use of devices and biofilm formation are critical determinants of CoNS, a general decision has to be addressed: whether to remove the foreign body and/or whether to initiate calculated antimicrobial treatment.[288,354]This also holds true for implant infections caused by CoNS, which remain a therapeutic challenge as they frequently result in failure of conservative antibiotic therapy and require withdrawal of the foreign device.[355]Therefore, for easy-to-change devices, the optimal treatment of a foreign body infection by CoNS is the removal of the device when possible and its replacement is still needed.[356,357,358,359]Regardless of the type of device, removal of implanted devices is recommended when the patient shows signs of severe sepsis, septic phlebitis, and septic shock. In some circumstances, salvage of the device is the preferred option. Foreign body infections associated with long-term or permanent catheters (e.g., Port-a-cath or Hickman-type catheter) may be treated successfully "through the line."[360]However, persistent or relapsing fever and other signs of treatment failure are clear indications for removal

of a medical device.[353]In the case of uncomplicated CoNS and foreign body infections—and provided that the device is removed—duration of parenteral therapy may be short (about 5 to 7 days).[355]If an intraluminal infection is suspected and the implanted device is retained, systemic antibiotic therapy for at least 10 to 14 days are recommended.[353]

Endocarditis that is caused by CoNS—depending on its resistance profile—is often treated with a combination of β-lactamase–resistant penicillin or vancomycin plus an aminoglycoside and/or rifampin.[354,361]In cases of prosthetic valve endocarditis, surgical removal of the infected prosthesis may be necessary to effect a cure.

Future Trends

Worldwide, CA-MRSA strains are a significant threat to healthy people of all ages and are of particular concern in young children. To make matters worse, these strains also spread rapidly from person to person. Two trends make the CA-MRSA strains even more challenging: their entry into the hospitals where they may establish as hospital "flora" and the potential for acquisition of further mobile elements (e.g., plasmids) carrying additional resistances and/or virulence factors.[34,362,363,364]Because prior viral infection may increase the patient's susceptibility to necrotizing pneumonia,[3]the next influenza pandemic could be devastating because of the severe course of MRSA pneumonia.

*S. aureus*strains predominantly associated with domestic animals, in particular with pigs, cattle, and poultry, are emerging rapidly in particular in areas with high prevalence of farming. In several Europe and Asian countries (e.g., The Netherlands, Germany, France, Singapore) and Canada, an unusual *S. aureus*lineage (MLST CC398; corresponding *spa*-types t011, t034, t108, and relatives; nontypeable applying usual PFGE protocols) was found, which was shared by animals, the farmers and veterinarians.[365]Recent findings suggest that this livestock-associated clonal lineage, which belongs to a separate biotype and comprises methicillin-susceptible as well as methicillin-resistant isolates, is quite virulent. LA-MRSA strains have been regularly cultured from patients with invasive infections caused by this pathogen.[36,37]Outbreaks with CC398 LA-MRSA were reported and some CC398 isolates have now been associated with the PVL toxin.[366,367]The import of MRSA CC398 from animal reservoirs into hospitals results in the spread of MRSA.[37,368,369]Thus, livestock has become an important source of MRSA. Increasingly, also patients without reporting contact to animals were found to be colonized or infected, with LA-MRSA reaching 15 percent or more in some European countries.[370,371]Matters of further concern include the observation of a *cfr*plasmid conferring transferable resistance against oxazolidinones that was found in MRSA CC398 background.[372]

The recent detection of a *mecA*homolog in livestock and clinical isolates of *S. aureus*—designated *mecC*—raises questions regarding the prevalence, burden, and impact of MRSA not detectable with available nucleic acid-based detection approaches.[8,9,94,95]One could

speculate that further *mecA*homologs may remain undetected and may circulate hidden in animal or patient populations.

Concerning non-*S. aureus*staphylococcal species, *S. lugdunensis*has been recognized as an emerging pathogen that is being more frequently recovered from patients. In addition to its generally accepted role as an aggressive cause of infectious native and prosthetic valve endocarditis and of various kinds of foreign body-related infections, there is increasing evidence that this CoNS species is also a usual cause of skin and soft tissue infections.[335,373,374]Recently, a case of necrotizing fasciitis has been reported.[375]Of utmost importance, optimized identification methods have to be applied to enhance *S. lugdunensis*detection.[335]Thus, often showing a more fulminant course, infections with *S. lugdunensis*tend to bear a resemblance to *S. aureus*infections rather than those caused by CoNS.[376]Besides SCVs, *S. lugdunensis*may show further colonial variation that delays identification by the clinical laboratory personnel.[336,377]Thus, *S. lugdunensis*may pose a serious challenge for the future.

Emergence of methicillin resistance in the coagulase-positive species *S. pseudintermedius*isolates recovered from animals in veterinary clinics around the world has been reported.[22]Probably underreported due to likely misidentification as *S. aureus*, the real importance of this species for human infections is unknown. However, human clinical cases, also with methicillin-resistant strains, have been reported.[378,379]The clinical impact of the recently described human-associated CoNS species, *S. pettenkoferi*, is currently not fully assessable.[380] However, several BSIs and other infectious entities have been increasingly described in the past years.[381,382]Finally, the emergence of CoNS strains with decreased susceptibility to glycopeptides will further narrow the spectrum of our therapeutic armamentarium.[280,383]

One of the most important questions is how safe our therapeutic options for the treatment of MRSA infections are in future. The certainly underdiagnosed hVISA status and the putative vancomycin creep phenomenon may further limit the therapeutic applicability of the glycopeptides. The therapeutic significance of the recently available MRSA-active cephalosporins has not yet been fully evaluated. All antibiotic agents introduced in the past decade on the market are restricted in their approval and feature meanwhile resistant isolates. Though the pipeline for antibiotics with Gram-positive activity might be not as empty as reported for compounds against Gram-negative microorganisms, the situation has to be considered as limited. Agents developed could include lipoglycopeptides such as dalbavancin, oritavancin, and telavancin or β-lactam combinations with "second-generation" β-lactamase inhibitors such as avibactam. Agents that ameliorate the effect of biofilm in medical devices are also an area of important research. All this demands a more careful, rationale usage of the antibiotic armamentarium active against staphylococci.

Abstract

*The genus*Streptococcus*encompasses a broad range of colonizing and pathogenic organisms. Streptococci inhabit animals as well as humans and can cause infection in both. They are found most abundantly as commensals in the mouth, gastrointestinal tract, and genitourinary tract. When pathogenic, they are important causes of skin and soft tissue infection, pharyngitis, pneumonia, and bacteremia. This chapter describes the microbiologic and clinical characteristics of the streptococci typically seen in human infection and emphasizes features of transmission and prevention.*

Key Concepts

- Streptococci are common commensal organisms.
- Streptococci are Gram-positive cocci growing in pairs or chains.
- More than 30 species of streptococci have been identified; classification is based primarily on patterns of hemolysis.
- Streptococci can be spread by both direct and indirect routes.
- *Streptococcus*species cause a variety of infections ranging from mild pharyngitis to severe necrotizing fasciitis.
- Resistance to antimicrobial agents is being reported with increasing frequency in some *Streptococcus*species (e.g., *Streptococcus pneumoniae*).

Background

Streptococci are Gram-positive, non–spore-forming spherical or ovoid bacteria (cocci) that grow in pairs or chains and can be distinguished from staphylococci by their inability to produce catalase.[1]Most streptococci are facultative anaerobes, though some may require strict anaerobic conditions for growth. There are more than 30 identified species of the genus *Streptococcus*; classification of streptococcal organisms depends on patterns of hemolysis, growth characteristics, biochemical reactions, and antigenic composition.[1,2]Streptococci cause a variety of diseases and conditions that depend on the species of organism present, the body site involved, and host factors. Basic principles of the major groups of streptococci are discussed next.

Basic Principles

GROUP A *STREPTOCOCCUS*

Group A *Streptococcus*(GAS) is among the most frequent and important pathogens found in humans. Spread of GAS occurs by direct person-to-person contact. Healthcare-associated outbreaks of streptococcal pyoderma, a purulent streptococcal infection of the skin, have declined substantially but still occur. Aggressive group A streptococcal infections associated with shock, bacteremia, and multiorgan failure are being reported with increasing frequency.[3]

Identification

GAS are Gram-positive cocci occurring in pairs or short chains (resembling a short string of beads). A negative catalase test result distinguishes streptococci from staphylococci.[1]Although facultatively anaerobic, most are oxygen tolerant and grow readily in air. When cultivated on blood agar plates, GAS appear as white-to-gray colonies, 1 to 2 mm in diameter, and are surrounded by clear, colorless zones within which the red blood cells in the medium have been completely lysed (β-hemolysis). GAS are presumptively distinguished from other β-hemolytic streptococci by their susceptibility to bacitracin.

Epidemiology and Transmission

Streptococcal pharyngitis is most common among children 5 to 15 years of age; however, all age groups are susceptible. GAS cause approximately 15 percent of all sore throats in children.[4,5]Spread of GAS occurs by direct person-to-person contact, probably by infected droplets of saliva or nasal secretions and perhaps by hand-to-hand-to-mouth contact.[4,5]Crowding (such as occurs in schools and military barracks) facilitates transmission and may account for the increased incidence of GAS infections in the colder months of the year. Fomites (contaminated clothing, blankets, dust) do not appear to play a significant role in disease transmission.[6]

Asymptomatic nasopharyngeal carriage of GAS occurs at a rate of 15 to 20 percent in school-age children and has been associated with transmission of infection. Adults are asymptomatically colonized with GAS at much lower rates. Those who carry the organism are more effective transmitters of disease if they have only recently become colonized and have a large number of streptococci recoverable from the throat. Foodborne and waterborne outbreaks of GAS infection are well documented.[7]Foodborne outbreaks have been associated with contamination of food by a streptococcal carrier and allowing the food to stand at room temperature.[7]

Streptococcal pyoderma is a purulent streptococcal infection of the skin. This infection typically occurs among economically disadvantaged children (aged 2–5 years) dwelling in tropical or subtropical climates; skin infections also are prevalent in northern climates during the summer months. Poor hygiene is a risk factor for the development of streptococcal pyoderma because GAS can initially colonize unbroken skin.[3,8] The mode of transmission of GAS pyoderma is poorly understood but likely includes skin-to-skin contact as well as transmission by fomites such as towels, shed skin scales, contaminated dust, and arthropod vectors.[8]

Erysipelas and cellulitis are also acute inflammatory GAS skin infections. Erysipelas often affects infants and persons older than 30 years, and GAS cellulitis may occur after trauma, including surgery.[8,9]

Healthcare-associated outbreaks of GAS skin infection have declined substantially with improved attention to infection prevention, but such outbreaks continue to be reported.[10] Outbreaks of GAS in nurseries,[11] among postpartum women,[12,13] or in surgical site infections[14] have been traced to healthcare personnel (HCP) who are nasopharyngeal, anal, or vaginal streptococcal carriers. Such infections constitute infection prevention emergencies because identification and treatment of the carrier can curtail the outbreak.[15] In addition to asymptomatic carriage, HCP with active streptococcal skin infections have been implicated in healthcare-associated transmission of GAS skin infections.[13] In addition to carriers, severe outbreaks of GAS have been linked to nonadherence to standard infection control practice in long-term and long-term acute care facilities.[16,17,18,19]

Aggressive GAS infections associated with shock, bacteremia, and multiorgan failure are being reported with increasing frequency [3,20] and occur at a rate of 3.5 cases per 100,000 persons in the United States.[21] Although risk factors for invasive GAS infections include the presence of surgical wounds, diabetes mellitus, and other underlying medical problems, there appears to be an increased incidence of cases in otherwise healthy young adults with minor, even trivial trauma.[3] Age and residence in long-term care facilities have been recently identified as risk factors for invasive infection.[10,19] Recent clonal outbreaks of GAS disease have also been described in communities, in long-term care facilities, and among family members.[10,22,23]

Diagnosis

Throat culture remains the gold standard for diagnosis of streptococcal pharyngitis.[22] However, a positive culture does not differentiate between acute infection and the asymptomatic carrier state. Rapid tests that identify group A carbohydrate antigen by latex agglutination or enzyme immunoassay are an alternative method of diagnosis.[24] In a patient with suggestive symptoms, a positive rapid antigen detection test (RADT) establishes the diagnosis of GAS pharyngitis, because this test is highly specific. Given the 80 to 90 percent sensitivity of this test, however, consideration should be given to performing a throat culture in a patient with pharyngitis who has a negative RADT for GAS.[4] Newer RADTs may have a sensitivity approaching that of throat culture, thus obviating the need for backup throat culture if the RADT is negative[4,25,26]

Serodiagnosis of a recent streptococcal infection can be made by detecting antibodies to streptococcal extracellular products. Three serologic tests in common use include assays for antistreptolysin O (ASO), anti-DNase B, and antihyaluronidase. These tests may be used in the diagnosis of acute rheumatic fever, a nonsuppurative complication of untreated streptococcal pharyngitis.[27]

Streptococcal skin infections are often diagnosed by sight. If an open wound is present, obtaining a culture may be appropriate. Diagnosis of invasive GAS infection is made by isolating the organism from blood or other normally sterile body fluid (spinal, synovial, peritoneal, or pleural) or by obtaining a tissue biopsy specimen in the setting of suggestive clinical signs and symptoms.

Clinical Infections

Manifestations of streptococcal pharyngitis include abrupt onset of sore throat accompanied by malaise, fever, and headache. Nausea, vomiting, and abdominal pain are common in children. Physical examination reveals an erythematous posterior pharynx with enlarged, hyperemic tonsils containing gray-white exudates. Tender, swollen submandibular lymph nodes are present, as well as a fever of 101°F (38.3°C) or higher. In the absence of complications, the pharyngitis is self-limited, and fever abates in 3 to 5 days. Patients with streptococcal pharyngitis who do not receive antibiotic therapy are at risk for developing late nonsuppurative complications, including acute rheumatic fever and poststreptococcal glomerulonephritis.[2,3,4,5]

Scarlet fever results from infection with a streptococcal strain that elaborates erythrogenic toxin.[2,3]When scarlet fever occurs, it is usually the result of pharyngeal infection, but it can occur in the setting of GAS skin infection or sepsis. It is characterized by a diffuse red rash that typically appears on the second day of illness, lends a sandpaper texture to the skin, and fades over the course of a week. It is followed by desquamation of the skin. Severe forms of scarlet fever with systemic toxicity and sepsis are rare in the antibiotic era.

Erysipelas is an acute inflammation of the skin and cutaneous lymphatic vessels. It manifests as well-demarcated areas of erythema and swelling that may advance rapidly.[8,9]Erysipelas commonly affects the face and in such cases may be preceded by GAS pharyngitis. It may occur on the trunk or extremities at a surgical site or wound and is often accompanied by chills, fever, and toxicity. Blebs and bullae may form on the affected areas of skin and leave raw, weeping wounds with rupture.

Streptococcal pyoderma, or impetigo, is a purulent skin infection that begins as papules and evolves to form vesicles and then pustules. The pustules enlarge and rupture over 4 to 6 days to form thick, "stuck-on," amber-colored crusts. Ulcerated lesions are known as ecthyma. Impetigo often occurs on multiple areas of exposed body sites, including the lower extremities, and remains well localized. Systemic symptoms are usually absent.[8]

Streptococcal cellulitis manifests as a warm, erythematous, edematous, and painful spreading inflammation of the skin and subcutaneous tissues.[8,9]Margins may advance rapidly but are not well demarcated or raised as in erysipelas. Cellulitis usually results from infection of an antecedent incidental or larger break in skin integrity (trauma, burns, surgery), and the organism may invade the lymphatics and bloodstream. Lymphangitis can accompany cellulitis and is characterized by red, tender streaks leading to tender, enlarged lymph nodes.

Necrotizing fasciitis (NF) is a severe invasive GAS infection involving the subcutaneous tissue extending to the fascia and fat, most commonly affecting the extremities.[3,8]NF typically begins at a site of often trivial trauma. Pain at the site of minor trauma may be the initial symptom. Within 24 hours the area becomes erythematous, swollen, warm, and tender. The infection and symptoms spread to involve adjacent tissues. Patients frequently report deep muscle pain or arthralgia in the area that appears out of proportion to the physical findings. Over the subsequent 24 to 48 hours, the affected areas take on a purple then blue coloration and blisters containing clear yellow fluid develop. Gangrene occurs after 4 to 5 days and is characterized by a well-demarcated area covered by a necrotic eschar and surrounding erythema. NF is often a fulminant illness with shock and multiorgan failure. It is a life-threatening illness with very high mortality in the absence of early and aggressive surgical debridement and antibiotic therapy.[9,28]

Although other bacteria are known to cause toxic shock syndrome (TSS), some cases can be related to streptococcal infections. Skin or mucous membranes are the portal of entry for streptococci in 60 percent of patients with TSS, with no definite portal of entry in the remaining 40 percent of patients. In the latter group, it is presumed that the source of infection is streptococci in the pharynx or intestine with transient bacteremia.[3,8]Suction lipectomy, hysterectomy, vaginal delivery, bunionectomy, and bone pinning have preceded streptococcal TSS in unpublished reports.[3,8]Soft tissue infection is evident in approximately 80 percent of patients and evolves to NF or myositis in 70 percent.[29]The early symptoms of streptococcal TSS include myalgias, malaise, chills, fever, nausea, vomiting, and diarrhea. This is followed by tachycardia, fever, tachypnea, and marked pain, which progresses out of proportion to the physical findings.[3,8]Confusion is present in half of the patients at presentation. Hypotension and shock frequently develop and are associated with multisystem organ dysfunction (particularly renal impairment and acute respiratory distress syndrome). Mortality is high (30 percent) despite aggressive treatment.[3,29]

Pathogenesis

Streptococci have surface molecules (M proteins, hyaluronic acid, and C5a peptidase) that allow evasion of phagocytosis and proliferation in tissues. Extracellular products released by GAS (DNases, hyaluronidase, streptokinase) facilitate liquefaction of pus and spread of streptococci through tissues.[3,28]

Dysregulation of the coagulation and anticoagulation pathways may occur in GAS infection, leading to a decrease in tissue perfusion, hypoxia, and subsequent tissue necrosis and organ failure. TSS is thought to be the result of "superantigen" production by GAS, the elaboration of extracellular toxins that cause widespread nonspecific activation of the immune system with subsequent marked inflammatory response.[30]

Treatment

Penicillin is the drug of choice in the treatment of streptococcal infections.[4]Penicillin resistance has not yet been identified in GAS infections. Failures of penicillin treatment for GAS pharyngitis are not uncommon despite the lack of resistance to penicillin, and some authors recommend cephalosporins as first-line agents for treatment of GAS pharyngitis.[4,31]Erythromycin is recommended for penicillin-allergic patients, but there have been reports of GAS resistant to erythromycin.[32,33]In addition, there have been recent reports of high-level fluoroquinolone resistance among GAS.[34]

In severe skin infections such as NF and myositis, early and aggressive surgical intervention is mandatory with drainage of the site, debridement, or, in some cases, fasciotomy or amputation. Penicillin appears to be less efficacious in the setting of fulminant streptococcal infection, and this may be the result of large inoculum size with slowed growth of the organisms; in such a situation there is lower expression of penicillin-binding targets.[3,8,9,28] In experimental models of myositis, antibiotics such as clindamycin and erythromycin appear to be more effective than penicillin, possibly related to the inhibition of toxin production by the former two drugs.[8,9] Rare cases of clindamycin resistance have been reported. Therefore, the combination of both penicillin and clindamycin is recommended to treat serious GAS infections, such as NF and TSS.[8,9]

Intravenous immunoglobulin (IVIG) may be a beneficial adjunctive therapy for TSS, because it is postulated to neutralize GAS toxin.[35,36] A recent randomized, placebo-controlled trial demonstrated a decrease in mortality with the use of IVIG, but because of the small number of patients enrolled, the difference in mortality between IVIG and placebo groups was not statistically significant.[35] The usefulness of this therapy requires further study.[36]

Prevention and Control

Infection prevention measures, including strict compliance with Standard Precautions including respiratory etiquette and hand hygiene between patients, appropriate precautions for infected patients, and aseptic technique, are useful in the prevention of healthcare-associated streptococcal infections.[37]

See Table 94-1 for information on Transmission-based Precautions. During outbreaks of GAS infection, transmission prevention and control measures may also include cohorting of cases and treatment of carriers. Some authors have advocated the use of prophylactic antibiotics for household contacts of serious GAS infections,[22] though the Centers for Disease Control and Prevention (CDC) does not recommend routine screening and prophylaxis in such situations.[38]

Table 94-1 Transmission-based Precautions for

Organism/Disease	Type of Precaution	Duration of Precautions	Comments
Pneumonia			
Streptococcus, Group A			
Adults	D	U 24 h	See Streptococcal Disease (group A *Streptococcus*) in next entry. Contact Precautions if skin lesions present.
Infants and young children	D	U 24 h	Contact Precautions if skin lesions present.
Pneumococcal pneumonia	S		Use Droplet Precautions if evidence of transmission within a patient care unit or facility.
Streptococcal Disease (Group A *Streptococcus*)			
Skin, wound, or burn			

Major	C, D	U 24 h	No dressing or dressing does not contain drainage adequately.
Minor or limited	S		Dressing covers and contains drainage adequately.
Endometritis (puerperal sepsis)	S		
Pharyngitis in infants and young children	D	U 24 h	
Pneumonia	D	U 24 h	
Scarlet fever in infants and young children	D	U 24 h	
Serious invasive disease	D	U 24 h	Outbreaks of serious invasive disease have occurred secondary to transmission among patients and HCP. Contact Precautions for draining wound as above; follow recommendations for antimicrobial prophylaxis in selected conditions.
Streptococcal Disease(Group B *Streptococcus*), Neonatal	S		
Streptococcal Disease(not Group A or B) unless covered elsewhere	S		

Precaution types: A, airborne ; C, contact; D, droplet; S, standard; when A, C, and D are specified, also use S. Duration of precautions: CN, until off antimicrobial treatment and culture-negative; DI, duration of illness (with wound lesions, DI means until wounds stop draining); DE, until environment completely decontaminated; U, until time specified in hours (h) after initiation of effective therapy; Unknown: criteria for establishing eradication of pathogen has not been determined.
Adapted from Siegel JD, Rhinehart E, Jackson M, et al. *2007 Guideline for Isolation Precautions: Preventing Transmission of Infectious Agents in Healthcare Settings.*Available at: **http://www.cdc.gov/hicpac/pdf/isolation/isolation2007.pdf**.

To prevent additional healthcare-associated GAS infections, enhanced surveillance and limited epidemiologic investigation are warranted following one episode of healthcare-associated GAS infection on a surgical or obstetric ward. After identification of a patient with postoperative or postpartum GAS, medical and laboratory records should be reviewed to identify other infections, and isolates from infected patients should be stored and surveillance heightened to identify additional episodes. Limited HCP screening should be undertaken. Most healthcare-associated transmission is traced to carriers involved in direct patient care; screening should include all HCPs who were present at the delivery, who performed vaginal examinations before delivery, who were present in the operating room during a procedure, and who changed dressings on open wounds.

Screening of HCPs should include culture of the nares, throat, vagina, rectum, and skin. HCPs may return to work pending culture results. Any HCP whose culture is positive for GAS should refrain from patient care for the first 24 hours of antimicrobial treatment. The regimen should be tailored to the carriage site; previous reports have indicated anal carriage may be difficult to eradicate. Appropriate treatment for a positive rectal culture may be vancomycin 250 mg orally four times a day and rifampin 600 mg orally twice a day for 10 days. For a positive throat, vaginal, or skin culture, appropriate

treatment may be penicillin 500 mg four times a day for 10 days with rifampin 600 mg orally twice a day for the last 4 days of the 10-day course.[10,15]

GROUP B *STREPTOCOCCUS*

Group B *Streptococcus*(GBS) is a common inhabitant of the lower gastrointestinal (GI) and genital tracts. Nonpregnant adults with underlying medical conditions are at increased risk for GBS infection. GBS can be transmitted vertically to newborns during labor and delivery, and apparently via breast milk. The use of intrapartum prophylaxis with antibiotics has led to a decline in the incidence of GBS neonatal infection. Early neonatal GBS infection occurs within the first 6 days of life and arises from GBS acquired from colonized mothers during delivery. Late neonatal infection occurs between 7 and 89 days and results from intestinal colonization.

Identification

*Streptococcus agalactiae*is the species comprising the Lancefield GBS. GBS exhibits β-hemolysis and grows facultatively. Colonies of GBS are gray-white and flat, and Gram stain reveals Gram-positive diplococci. Latex agglutination or other immunologic methods are used to detect group B-specific cell wall antigen for identification of the organism. GBS are also characterized by resistance to bacitracin and trimethoprim-sulfamethoxazole and can be distinguished from group D streptococci by an inability to hydrolyze esculin.[39]

Epidemiology and Transmission

GBS are common inhabitants of the lower GI and genital tracts, and studies have demonstrated a genital/lower GI tract colonization rate of more than 20 percent in women.[39]A recent prevalence study of GBS in male and nonpregnant female college students demonstrated that 34 percent of women and 31 percent of males were colonized, with tampon use in women being a risk factor for colonization.[40]

Pregnancy alone does not affect the prevalence of GBS colonization, but diabetes mellitus has been associated with higher colonization rates in pregnant women.[41]Sexual activity is a risk factor for GBS colonization,[42]and multiparous women and those over 20 years of age have lower genital colonization rates.[39]Nonpregnant adults with diabetes mellitus, human immunodeficiency virus (HIV) infection, malignancy, and chronic liver disease are at increased risk for GBS infection.

GBS can be transmitted vertically to newborns during labor and delivery,[42]and there has been apparent transmission via breast milk.[43]In nonpregnant adults, transmission can occur through direct contact, including via sexual contact.[40]GBS has been transmitted from person to person in hospitals, particularly under conditions of crowding and poor hand washing.[39]

Diagnosis

The diagnosis of invasive GBS infection is made by isolating the organism from blood, cerebrospinal fluid (CSF), or other normally sterile body sites. Recovery of the organism from mucous membranes is typically indicative of colonization rather than infection. Screening of pregnant women for the presence of GBS colonization requires both vaginal and rectal cultures.[24]Tests that detect GBS antigen are available but are not sensitive enough to reliably identify maternal GBS colonization[24]and, in general, are not thought to be of sufficient sensitivity and specificity to establish a diagnosis of GBS infection.[40]

Polymerase chain reaction detection of GBS nucleic acids is being investigated as a more rapid and sensitive alternative to culture.[44]

Clinical Infections

GBS neonatal infections are associated with increased morbidity and mortality. GBS invasive infection typically occurs within the first week of life (early-onset disease), and initial case series reported mortality rates as high as 50 percent, which has declined to 4 percent in recent years.[45,46,47]

Manifestations can include pneumonia, sepsis, meningitis, and bone/joint infection. Meningitis is more common in late-onset GBS infection, which occurs from 1 week to 3 months after birth.[45,46,47]Risk factors for GBS neonatal infection in infants born to colonized mothers include preterm delivery, prolonged membrane rupture during labor, maternal fever during labor, and maternal history of prior infant with GBS sepsis. Rates of neonatal GBS diseases decreased 33 percent from 2003 to 2005, but incidence among black infants increased 70 percent, suggesting racial disparity in prenatal care.[42]

GBS infections during pregnancy are not uncommon.[48]Urinary tract infection due to GBS occurs in 2 to 4 percent of pregnancies.[24]Amnionitis, endometritis, sepsis, or meningitis can also occur in pregnant women, and GBS infection may account for 15 to 25 percent of cases of peripartum fever.[39]

Primary bacteremia without a focal site of infection occurs with GBS infection and carries a high mortality.[39]GBS endocarditis usually occurs in the setting of valvular heart disease and predominantly affects adults over 50 years of age; more than half of patients have an underlying medical condition such as diabetes mellitus, HIV, cirrhosis, neoplasia, or immunologic disease.[39,49]GBS endocarditis is characterized by rapid destruction of the affected valve(s), large vegetations, frequent embolization, and a 50 percent mortality rate.[39,49]

Soft tissue infection is the most common site of focal GBS disease and manifests as cellulitis, foot or decubitus ulceration, and skin abscess, especially in patients with underlying diabetes. More severe disease can occur in the form of pyomyositis or NF, particularly in patients with underlying medical illnesses such as diabetes mellitus.[39,50]

GBS is a significant cause of pyogenic arthritis in nonpregnant adults, typically occurring in middle-aged persons with coexisting illnesses such as diabetes mellitus, malignancy, or liver disease.[51]A high case-fatality rate is associated with these infections. Meningitis is also seen in patients with underlying comorbid conditions and has a mortality rate of 34 percent.[39]

Pathogenesis

In GBS neonatal infections, heavy maternal colonization is associated with an increased risk for preterm labor, which in turn is a significant risk factor for neonatal infection.[39]Intrauterine infection of the fetus therefore likely occurs via ascending spread of GBS from the vagina of a pregnant, asymptomatically colonized woman and subsequent rupture of membranes before 37 weeks' gestation.[24,39]Infants can also become infected during passage through the vaginal canal during childbirth. Neonates with invasive GBS infection display lower titers of maternal antibodies to GBS than healthy neonates whose mothers are colonized with GBS.[39]

The source of GBS infection in the nonpregnant adult and in late neonatal sepsis appears in most cases to be endogenous respiratory, genitourinary, or GI colonization.[39] Virulence factors include capsular polysaccharide, β-hemolysis, C5a peptidase, adhesions, and immunogenic surface proteins.[52]

Treatment

Penicillin is the drug of choice for treatment of GBS infection. Cardiac surgery is usually required for treatment of GBS endocarditis.[49] Antimicrobial resistance of GBS to penicillin has not been described to date.[24] There is increasing resistance to erythromycin and clindamycin, however.[45,53]

Prevention

The use of intrapartum prophylaxis with antibiotics has led to a 70 percent decline in the incidence of GBS neonatal infection since the early 1990s, and a 33 percent decline since 2000 and 2001,[42,54] though GBS disease continues to cause illness and death among newborns.[24] A recent study showed that the risk of neonatal GBS disease decreased by half by culturing all women for GBS at 35 to 37 weeks' gestation and giving intrapartum prophylaxis to carriers, compared with using prophylaxis only if women present in labor with fever, prolonged rupture of membranes, or preterm delivery.[54] These findings led to a recent revision of the original 1996 guidelines on prevention of perinatal GBS infection issued by the CDC.[24] The 2010 guidelines still recommend universal prenatal screening of all pregnant women at 35 to 37 weeks' gestation for vaginal and rectal GBS colonization and intrapartum prophylaxis of colonized women using penicillin. Women with GBS bacteriuria during pregnancy or those who have previously given birth to an infant with GBS disease should also receive intrapartum prophylaxis.[24]

Although these recommendations have resulted in decreased neonatal infections, there remains concern that the increased use of antibiotic prophylaxis for GBS could ultimately lead to an increase in prevalence of GBS or non-GBS neonatal infections due to organisms resistant to penicillin.[24,55] The cost-benefit ratio of this strategy has also been questioned.[56] Vaccines for use in pregnant women that would prevent GBS neonatal infection are under study.[57,58]

Standard Precautions are recommended for prevention of healthcare-associated transmission of GBS; proper hand hygiene will decrease the risk of cross-contamination (see Table 94-1).

STREPTOCOCCUS PNEUMONIAE

S. pneumoniae is the most common cause of community-acquired pneumonia, the most common cause of bacterial meningitis in adults, and the second most common cause of bacterial meningitis in children.[59] It is also the most commonly isolated pathogen in otitis media and acute sinusitis. Two vaccine formulations are available. One is a 23-polyvalent vaccine recommended for all persons aged 65 years and older and anyone aged 2 to 64 years with medical conditions putting them at risk of pneumococcal infection; the other vaccine is a conjugated vaccine and is recommended for all persons aged 2 years and older who have medical conditions that place them at risk for pneumococcal disease. (See following section on Prevention.)

Identification

On Gram stain, pneumococci appear as lancet-shaped Gram-positive diplococci. Colonies of pneumococci have a mucoid or smooth appearance on blood agar as a result of their polysaccharide

capsule and are surrounded by a zone of partial hemolysis with a greenish discoloration, known as α-hemolysis. Identification is confirmed by the presence of bile solubility and susceptibility to optochin.[59]

Epidemiology and Transmission

Serious pneumococcal infection is most prevalent in the very young and very old. Patients with bronchopulmonary disease or underlying conditions that compromise immunity are predisposed to pneumococcal infections. Pneumococci are transmitted from person to person through close contact, and infection results from the microaspiration of organisms colonizing the nasopharynx; 5 to 10 percent of healthy adults and 20 to 40 percent of healthy children are colonized with pneumococci,[59]so hospitalized patients do not require isolation. Epidemics of pneumococcal pneumonia occur especially under conditions of crowding and poor ventilation.[60,61]Healthcare-associated pneumococcal infection, particularly pneumonia, can occur, particularly in the elderly or persons with comorbid illnesses.[62]

Pneumococcal infection in this setting may arise from the patient's own flora acquired before admission or through horizontal spread after admission.

Diagnosis

A presumptive diagnosis of pneumococcal pneumonia in a patient with compatible signs and symptoms is strongly suggested by the presence of polymorphonuclear leukocytes and Gram-positive diplococci in sputum specimens along with isolation of *S. pneumoniae*in sputum culture.[59]Definitive diagnosis requires isolation of *S. pneumoniae*from blood cultures in the presence of a new pulmonary infiltrate. Approximately 25 percent of patients with pneumococcal pneumonia will have positive blood cultures, though these data are from the preantibiotic era.[59]A urine test that detects pneumococcal polysaccharide can allow rapid diagnosis of pneumococcal pneumonia, and polymerase chain reaction on respiratory secretions is under investigation.[63]

The diagnosis of pneumococcal meningitis may be made by CSF Gram stain and culture or detection of capsular polysaccharide antigen in the CSF via latex agglutination. The latter test may have some use in patients who have received antibiotics before lumbar puncture and have negative CSF Gram stain and culture.[59]

Clinical Infections

Pneumococcal pneumonia is characterized by an often abrupt onset of fever, chills, pleuritic chest pain, and cough productive of rust-colored sputum. Patients usually appear ill with fever to 102°F to 103°F (38.9°C–39.4°C). Subsegmental lobar consolidation is seen on chest radiography in a majority of cases. Empyema (infection of the pleural space) is the most common complication of pneumococcal pneumonia and occurs in 2 percent of cases.[59]

The clinical signs and symptoms of pneumococcal meningitis are similar to those seen in cases of bacterial meningitis caused by other organisms. The greatest mortality occurs in patients at extremes of ages and is estimated at 20 to 60 percent.[59]The rates of pneumococcal meningitis in children and nonimmunized adults have decreased substantially since introduction of the pediatric 7-valent conjugated pneumococcal vaccine.[64,65]

Otitis media and sinusitis are other common manifestations of pneumococcal infection. Less-common clinical syndromes include conjunctivitis, endocarditis, purulent pericarditis, septic arthritis, and soft tissue

infection.[59]

Pathogenesis

Pneumococcal colonization of the nasopharynx is common and can be found in up to 60 percent of young children in day care.[59]Once colonization is present, infection can occur when pneumococci move into other areas of the body. Pneumococcal pneumonia, for example, is thought to result from the microaspiration or inhalation of organisms colonizing the nasopharynx. Ciliary clearance mechanisms can remove organisms that enter the sinuses, lungs, or eustachian tubes. Clearance mechanisms can be impaired through smoking, chronic obstructive pulmonary disease, or acute viral infection (e.g., influenza), leading to an increased risk for pneumococcal infection.[59]

Anticapsular antibody is protective against pneumococcal infection, and thus persons with diminished antibody responses to pneumococcus are also at increased risk for infection. Such risk groups include persons with multiple myeloma, HIV infection, and lymphoma. Persons with diabetes mellitus, malnutrition, alcoholism, chronic liver or kidney disease, and sickle cell disease also have a higher incidence of pneumococcal infection than the general population because of a variety of defects in immunity to pneumococcus. Pneumococcal meningitis arises from bacteremic spread to the meninges from another site of colonization or infection.[64]

Treatment

Penicillin G has traditionally been the antimicrobial agent of choice in patients with pneumococcal infection. Recently, however, strains have emerged that are resistant to penicillin and to other antibiotics.[66,67]As discussed below, the trends in antibiotic resistance in pneumococci have reversed since introduction of the conjugated pneumococcal vaccine.[68]Despite resistance, β-lactam antibiotics have been effective for invasive nonmeningeal infections caused by penicillin-resistant pneumococci.[69]Empiric regimens for pneumococcal infection should be based on the prevalence and patterns of drug resistance among pneumococcal isolates in the community.[70]Empiric combination therapy with vancomycin and an extended-spectrum cephalosporin (ceftriaxone or cefotaxime) is recommended for treatment of life-threatening pneumococcal infection (e.g., meningitis) until results of culture and susceptibility testing are known.[71]

Development and Impact of Resistance to Antimicrobial Agents

Penicillin-resistant strains of *S. pneumoniae* are being reported with increasing frequency. Resistance to penicillin is often accompanied by resistance to other antimicrobial agents,[66]including newer-generation fluoroquinolones,[67]though the overall prevalence of newer-generation fluoroquinolone-resistant pneumococci remains low in the United States. Most strains are resistant to older fluoroquinolones, such as ciprofloxacin.[67,72]Resistant strains exhibit altered penicillin-binding proteins that have reduced affinity for penicillin.[59]These strains appear to have emerged by human-to-human spread of a few clonal groups of multiresistant pneumococci. Infection with penicillin-resistant pneumococcal strains occurs with increased frequency in children (particularly those in day care); persons who are elderly, alcoholic, or immunosuppressed; and those previously receiving antimicrobial therapy.[59]The prevalence of these resistance strains has decreased since wide use of conjugated pneumococcal vaccination in children.[68]

Prevention

A vaccine containing polysaccharide from 23 serotypes of *S. pneumoniae*is available and covers 85 to 90 percent of serotypes causing bacteremic pneumococcal disease in the United States.[73,74]The vaccine has been proven effective in preventing pneumococcal bacteremia, but not pneumococcal pneumonia, in older adults.[75]The polysaccharide vaccine is recommended for all persons aged 65 years and older. It is also recommended for all persons aged 2 years and older with medical conditions placing them at risk for pneumococcal disease, including sickle cell disease, asplenia or splenic dysfunction, chronic renal or liver disease, chronic pulmonary or cardiovascular disease, organ transplantation, HIV infection, immunosuppressive drug therapy, alcoholism, or nasopharyngeal CSF leak. Revaccination after 5 years should be performed if there is ongoing risk for pneumococcal infection.[73,74]

The polysaccharide 23-valent vaccine is not effective in children under 2 years of age. A heptavalent conjugate vaccine was recently introduced for use in this population, and it can significantly reduce the incidence of otitis media, meningitis, pneumonia, and invasive pneumococcal disease in children,[64,76,77,78]and epidemiologic data suggest there may be a secondary decline in invasive pneumococcal disease among nonvaccinated adults.[77]Conjugate vaccines reduce nasopharyngeal carriage of vaccine-type strains, though they increase the frequency of carriage of nonvaccine-type strains.[76]Infections due to nonvaccine strains have increased in prevalence since introduction of the conjugated vaccine; this will have implications for future vaccine development.[68,79]

Patients with pneumococcal pneumonia may be cared for using Standard Precautions, though Droplet Precautions are recommended if there is evidence that transmission has occurred within a facility[37](see Table 94-1).

VIRIDANS *STREPTOCOCCUS*

The α-hemolytic and nonhemolytic streptococci other than pneumococci or enterococci are often referred to collectively as the viridans group of streptococci. The term "viridans" refers to the green-colored α-hemolysis that occurs when these organisms are cultured on blood agar. Some of the clinically significant species of viridans streptococci include *S. sanguis, S. salivarius, S. mitis*, and the *S. mutans*group.

Identification

Antigenic analysis of many strains has led to the recognition of a number of immunologic varieties, but only a few are classified into the Lancefield groups (A to O). Viridans streptococci can be distinguished from pneumococci by their bile insolubility and resistance to optochin and from enterococci by their inability to grow in 6.5 percent sodium chloride.[80]Viridans streptococci are fastidious with respect to their nutritional growth requirements, though most strains grow well in blood culture media.[80]The clinically significant species of viridans streptococci can be distinguished by a variety of biochemical tests,[80] though more recently they have been defined on the basis of genetic relatedness through molecular techniques.[81]

Epidemiology and Transmission

Viridans streptococci comprise a large percentage of the flora of the oral cavity and, for example, make up 28 percent of the flora of dental plaque and 45 percent of the flora from the tongue.[80] In addition, they colonize the GI tract and female genital tract and can be part of the skin flora.[80]

The incidence of viridans streptococcal bacteremia is increasing in patients with neutropenia secondary to cancer or bone marrow transplantation (BMT), and viridans streptococcal bacteremias have occurred in 12 to 18 percent of neutropenic transplant recipients.[81] BMT recipients are at particularly high risk, especially patients under 18 years of age, patients undergoing autologous BMT, and patients with a primary diagnosis of acute lymphocytic leukemia.[81,82,83,84,85] Although the recent trend toward use of autologous peripheral blood stem cell transplantation in combination with growth factors significantly reduces the duration of neutropenia, this technique, even with the use of prophylactic ampicillin, has not reduced the incidence of viridans streptococcal infection.[84] In patients with neutropenic cancer, the presence of mucositis, treatment with high-dose cytosine arabinoside, and prophylaxis with a fluoroquinolone or trimethoprim-sulfamethoxazole all have been identified as risk factors for the development of viridans streptococcal bacteremia.[81,83]

Diagnosis

Although a single positive blood culture for viridans species may be associated with either insignificant transient bacteremia or contamination, persistently positive blood cultures suggest the possibility of endocarditis.[80] In the absence of recent antibiotics, the sensitivity of blood cultures in identifying viridans streptococci causing endocarditis is 96 percent for the first set and 98 percent after two sets of blood cultures.[80]

Clinical Infections

Dental caries is one of the most common manifestations of disease due to viridans streptococci. In the preantibiotic era, viridans streptococci caused 75 percent of cases of endocarditis but currently account for 30 to 40 percent of cases.[80] The clinical course of viridans streptococcal endocarditis is typically subacute and occurs most often in patients with underlying valvular heart disease.

In patients with bacteremia, fever is usually present, and the majority of patients have concomitant oral inflammation/mucositis.[80,81,84] Up to 25 percent of patients with viridans streptococcal bacteremia after BMT can develop a toxic shock-like syndrome with hypotension, rash, and acute respiratory distress syndrome.[81,85] The mortality rate of viridans streptococcal bacteremia in immunocompromised persons has been as high as 12 percent despite adequate antibiotic therapy.[80]

Pathogenesis

Viridans streptococci are organisms of low virulence and do not have endotoxin or produce toxins.[80]

Extracellular dextran allows the organisms to adhere to cardiac valves, leading to endocarditis, and viridans streptococci can use sucrose to produce polysaccharides known as glucans that allow adhesion to dental surfaces.[80] The *S. mutans* genome was recently sequenced and found to contain additional virulence genes, including adhesins, proteases, and genes for acid tolerance.[86]

Treatment

Penicillin G has been the drug of choice for viridans streptococcal infections. The combination of penicillin G and gentamicin is synergistic in the treatment of endocarditis and can shorten the course of therapy.[80]Alternatives for penicillin-allergic patients include cephalosporins and vancomycin.

Resistance of viridans streptococci to a number of antibiotics has been increasing, and susceptibility to penicillin can no longer be assumed.[84]A study of 352 isolates of α-hemolytic streptococci revealed that 13 percent demonstrated high-level penicillin resistance, and 43 percent had intermediate resistance to penicillin.[87]Furthermore, a significant percentage of these isolates were also resistant to cephalosporins and erythromycin. Resistance to penicillin and other antibiotics varies among different species of viridans streptococci; therefore, antimicrobial susceptibility testing is important in determining the optimal treatment of viridans streptococcal infections.[80]Speciation and antimicrobial susceptibilities in some laboratories may require special request by managing physicians.

Prevention

Antibiotic prophylaxis against viridans streptococcal infection in patients with neutropenic cancer is controversial because not all studies have shown efficacy,[82]and the routine use of prophylaxis for patients with neutropenia is not recommended.[81]Furthermore, the use of prophylactic antibiotics in this setting has resulted in the emergence of resistance.[81]For example, bacteremia due to viridans streptococci with diminished susceptibility to fluoroquinolones has occurred in stem cell transplant recipients during levofloxacin prophylaxis for neutropenia.[88]

OTHER LARGE-COLONY B-HEMOLYTIC STREPTOCOCCUS

Group C streptococci (e.g., *S. equi, S. equisimilis*, and *S. zooepidemicus*) are common inhabitants of many animals, including horses, cows, dogs, and birds and can cause significant infections in these animals. Human infections may result from contact with infected animals or animal products. Certain species of group C streptococci can be part of the normal human nasopharyngeal and genital tract flora.[80]

Identification

On blood agar, these organisms grow in large colonies surrounded by a zone of β-hemolysis. Most of these organisms are classified within the Lancefield groups C or G and are less likely to be susceptible to bacitracin than are GAS.[80]

Epidemiology and Transmission

Group G streptococci can colonize the human nasopharynx, skin, and intestinal tract. Infections due to group G streptococci appear to be increasing in frequency and are often seen in the elderly or in patients with underlying malignancy.[80,89]Outbreaks of group G pharyngitis have been reported and in some cases have been thought to be foodborne.[80]Outbreaks, including those of healthcare-associated origin, of cellulitis, and from wound infections due to group C and G streptococci have been reported, with infections resembling those caused by GAS.[90]

Diagnosis

The diagnosis of group C or G streptococcal infection is typically made by recovery of the organisms on culture. Infection due to certain species of group C and G streptococci may result in an elevated ASO antibody titer.[80]

Clinical Infections

Clinical infections are often severe and resemble those caused by group A and B streptococci. Manifestations of clinical disease include pharyngitis, skin and soft tissue infection, septic arthritis, osteomyelitis, bacteremia and endocarditis, and meningitis. In addition, both group C and G streptococci have been associated with puerperal sepsis and endometritis as sporadic cases or epidemic outbreaks.[80]

Pathogenesis

Groups C and G streptococci appear to produce exotoxins and superantigens similar to those of GAS, perhaps explaining some of the likeness to GAS in disease manifestations.[80]

Treatment

Infections due to groups C and G streptococci usually respond well to penicillin G. Other antimicrobial agents active against these organisms include cephalosporins, erythromycin, and vancomycin.

MINUTE-COLONY *STREPTOCOCCUS*

Minute-colony streptococci form colonies that are very tiny (< 0.5 mm) and may have any of the three hemolytic patterns on blood agar.[91]This genetically heterogeneous group of organisms is often referred to as the *S. anginosus-milleri* group or the *S. intermedius*group and includes *S. intermedius, S. constellatus*, and *S. anginosis*. Unlike large-colony streptococci, these organisms are microaerophilic or anaerobic and usually occur in mixed infections with other organisms. A characteristic caramel-like odor on agar cultures is helpful in confirming the presence of the organisms.[92]

Epidemiology and Transmission

These organisms may be found among the normal oral and pharyngeal flora, as well as the GI tract. Minute-colony streptococci tend to cause pyogenic infections with abscess formation, differentiating them from other viridans streptococci.

Diagnosis

Organisms with typical colony morphology and microaerophilic/anaerobic growth can be cultured from sites of infection. Differentiation from other streptococci is based on biochemical testing.

Clinical Infections

Minute-colony streptococci tend to cause pyogenic infections with abscess formation, differentiating them from other viridans streptococci. The most common infections associated with the minute-colony streptococci are liver, abdominal/pelvic, lung, and brain abscesses.[91,93]Bacteremias are often the result of a concurrent suppurative focus of infection, such as a visceral abscess.[91]Cancer and alcoholism have been shown to be risk factors for bacteremia, and pulmonary infections and dental procedures may predispose to head and neck infections due to minute-colony streptococci. Central nervous system infections have been associated with congenital heart disease, sinusitis, and otitis media.[92]

Pathogenesis

The portal of entry for the organisms often involves trauma to a mucosal barrier, as in GI bleeding,[93] or, in the case of lung abscess, can be the result of aspiration.[92] Minute-colony streptococci can grow well in acidic environments, such as those found in abscesses, and produce hydrolytic enzymes that may facilitate spread of infection and production of pus.[92] In vitro studies have shown synergistic growth between minute-colony streptococci and oral anaerobes.[92]

Treatment

The mainstay of treatment for these organisms is penicillin G. Vancomycin, clindamycin, and cephalosporins are also active. Resistance among minute-colony streptococci to penicillin is uncommon but has been described, particularly among *S. anginosus* and *S. intermedius*.[92] Reduced susceptibility to third-generation cephalosporins has also been noted among some strains.[94] In addition to antimicrobial therapy, drainage of abscesses is an important aspect of treatment.

NONENTEROCOCCAL GROUP D *STREPTOCOCCUS*

The nonenterococcal group D streptococci, for the most part, exhibit α-hemolysis or no hemolysis. They can be distinguished from group D enterococcus by their inability to grow in high salt concentrations. The most common nonenterococcal group D Streptococcus to cause human infection is *S. bovis*.

Epidemiology and Transmission

Bacteremias due to *S. bovis* are frequently associated with GI malignancy and chronic liver disease. Fecal carriage of *S. bovis* is more common in patients with malignant colon lesions compared with healthy persons, in whom *S. bovis* colonization is rare.[95] Chronic liver disease appears to be another predisposing factor for *S. bovis* bacteremia.[95]

Clinical Infections

The most important clinical infections caused by *S. bovis* are bacteremias and endocarditis. Evaluation of the GI tract is recommended for persons with *S. bovis* bacteremia to exclude the presence of malignancy.[96]

Pathogenesis

The GI tract is the usual portal of entry for *S. bovis*, though the biliary and urinary tracts and dental procedures may be sources of entry in some cases.[96] Endocarditis typically occurs in the setting of abnormal or prosthetic heart valves.

Treatment

Penicillin is the treatment of choice. Cephalosporins or vancomycin may be used in penicillin-allergic patients.

Conclusions

The *Streptococcus* genus encompasses a variety of organisms causing mild to severe clinical infections. *Streptococcus* species are often found as commensals in humans and animals and therefore are difficult

if not impossible to avoid. Several control measures can be used to prevent the spread of organisms from person to person, the most important of which is hand washing. Vaccines are used for prevention of infection from several *Streptococcus*species but are not available for most organisms. Resistance to antimicrobial agents has been reported in some species and is of increasing concern. As patient populations age and the number of immunocompromised patients increase, infections with *Streptococcus*species will become increasingly important from an epidemiological standpoint. Penicillin remains the drug of choice in the treatment of most streptococcal infections, though there is increasing evidence of antimicrobial resistance in some strains.

Future Trends

Current research on streptococcal infections focuses primarily on prevention of infection through vaccine use and development. A vaccine for use in pregnant women that would prevent GBS neonatal infection is currently under study. Several vaccine candidates for the prevention of GAS infections are in various stages of development.[97]

In addition, a new conjugate vaccine appears to be decreasing the incidence of invasive pneumococcal disease in children. Some evidence suggests that there may be a secondary decline in invasive pneumococcal disease among nonvaccinated adults. The emergence of infections caused by nonvaccine strains of pneumococci deserves further study.

International Perspective

*Streptococcus*infections are seen worldwide and are epidemiologically important in most countries. The international community should continue to share information about resistance trends, prevention strategies, and outbreaks.[97]

Abstract

*Tuberculosis remains a significant infection in the United States and around the world. Patients infected with*Mycobacterium tuberculosis *can have an asymptomatic infection that can be persistent (latent tuberculosis infection), progressive primary disease, or—years (even decades) later—a reactivation leading to active disease. In most cases, tuberculosis is transmitted from patients with pulmonary or laryngeal disease through airborne droplet nuclei. Prevention of tuberculosis is based on detection of cases, airborne isolation in appropriate negative pressure rooms, respiratory etiquette, use of N95 respirators, and early and complete treatment of tuberculosis cases based on susceptibility testing. Patients with active tuberculosis must be treated for long periods. Many persons infected with*M. tuberculosis *have no signs and symptoms and are said to have latent tuberculosis infection. The tuberculin skin test and the interferon gamma release assays can be used to diagnose latent tuberculosis infection. Persons with latent tuberculosis infection may warrant treatment to prevent the development of active disease.*

Key Concepts

- Tuberculosis is present worldwide. It is estimated that about one-third of the world's population is infected with tuberculosis.
- The rise of tuberculosis in the United States in the late 1980s and early 1990s, with several documented hospital outbreaks of active tuberculosis and tuberculin skin test conversions, led to a

renewed appreciation for the need for aggressive measures to control tuberculoisis in healthcare institutions.

- *M. tuberculosis*, the causative agent of tuberculoisis, is an aerobic, acid-fast bacillus. People are infected with *M. tuberculosis*primarily via inhalation.
- Novel and highly specific molecular testing based on nucleic acid analysis to facilitate early detection of tuberculosis infection are available and validated in high prevalence countries. It also allows for detection of rifampin resistance.
- Patients diagnosed with latent tuberculosis infection should receive therapy to prevent future tuberculosis reactivation. A course of therapy with isoniazid alone for 9 months or the combination of weekly rifapentin and isoniazid for 12 weeks are recommended alternatives.
- Multidrug-resistant tuberculosis and extensively drug-resistant tuberculosis strains have emerged in recent years and are more difficult to treat.
- Nontuberculous mycobacteria can cause a variety of diseases, including pulmonary, skin, and soft tissue infections, especially in immunocompromised individuals.

Background

The highest incidence rates of active tuberculosis (TB) occur in Africa (363 cases per 100,000 people) and Southeast Asia (180 cases per 100,000 people in 2006).[1]Because of aggressive control efforts and implementation of the World Health Organization's (WHO's) Stop TB global initiative, the incidence per capita of TB has declined globally, but this has been offset by an increase in the number of cases resulting from population growth.

Case rates for TB in the United States declined from the 1930s through the early 1980s, with the near eradication of TB in the country predicted by the turn of the century.[2]However, rates of TB actually rose in the United States from 9.3 cases per 100,000 people in 1985 to 10.5 cases per 100,000 in 1992.[3,4,5,6]The rise in TB during the 1980s and early 1990s correlated with the human immunodeficiency virus (HIV) epidemic.[7]

In New York City, cases of TB declined to historic low levels in 1978 but then began to increase and peaked in 1992.[8]Fires in the Bronx decreased the number of available rental homes and increased overcrowding. Shelters were markedly overcrowded and drug abuse increased, and New York City had one of the highest rates of acquired immunodeficiency syndrome (AIDS) in the country.[8]The rate of drug-resistant TB increased from 6 to 7 percent to 25 percent of infections in 1992.[8]Furthermore, even among those with previous positive tuberculin skin testing (TST), reinfection with drug-resistant organisms was thought to be an important contributor to transmission. By 1994, 20 healthcare personnel had acquired multidrug-resistant TB (MDR-TB); 45 percent of them died. The high incidence of disease was finally curbed and controlled by implementation of expanded treatment regimens, increasing coverage of direct observed therapy (DOT, including involuntary detention and administration of therapy when needed), and implementation of Centers for Disease Control and Prevention (CDC) recommended infection control interventions.[8]

The increase in TB led to renewed vigor in diagnosing and treating patients with TB. This intervention led to a progressive decline in the rate of TB in the United States. By 2011 the rate of TB was 3.4 per 100,000, a decline of 5.8 percent from 2010. TB cases among foreign-born persons comprised 62 percent of the cases in the United States, with a rate of 17.2 per 100,000 in foreign-born versus 1.5 per 100,000 in U.S.-born individuals. The number of TB cases in the United States has decreased by 62 percent since 1992. However, the percentage of TB cases in foreign-born persons has continued to increase since 1993. Six extensively drug-resistant TB (XDR-TB, defined as TB resistant to INH, rifampin, any fluoroquiolone, and at least one of the injectable second line drugs [amikacin, kanamycin, or capreomycin]) cases were reported in 2011.[9]

The proportion of cases that received at least INH, rifampin, and pyrazinamide increased from 72 percent in 1993 to 88 percent in 2011, with the proportion of patients completing therapy increasing from 64 percent to 88 percent in 2009.[9]

Implementation of the CDC's TB infection prevention recommendations may have led to fewer reports of healthcare-associated outbreaks of TB.[8,10]

Mycobacterium Tuberculosis

TB is produced by the *Mycobacterium tuberculosis*(MTB) complex, which includes *M. tuberculosis, M. bovis, M. canetti, M. africanum, M. microti, M. caprae,M. pinnipedii,*and *M. mungi.*MTB is the most common causative agent of TB in the United States. MTB is an aerobic, poorly staining Gram-positive bacillus. Like other mycobacteria, it is acid-fast, meaning that certain stains, such as Kinyoun or Ziehl-Neelsen, will not decolorize with acid-alcohol. Mycobacteria are not unique in this property. Other organisms, such as *Nocardia*spp., *Rhodococcus*spp., and *Legionella micdadei*may also stain with acid-fast stains under some conditions. Nevertheless, the abbreviation AFB, for acid-fast bacilli, is frequently considered to be synonymous with mycobacteria.[11]

PATHOPHYSIOLOGY

TB is usually transmitted through airborne particles, usually 1 to 5 µm in size, that are generated by individuals with pulmonary and laryngeal TB.[10,12]When produced indoors (i.e., hospital room), these particles may be suspended in the air for prolonged periods of time and travel through the ventilation system of the building to infect susceptible individuals located in other areas.[12,13]The infectious droplet can go to the alveoli, be phagocyted by macrophages (where MTB can survive), produce local infection, and, in some cases, disseminate. The mycobacteria first spread to the regional lymph nodes and subsequently disseminate throughout the body. Although the person may have some mild symptoms, the initial infection usually goes unrecognized. During this stage of initial infection, the individual is not contagious unless active disease develops. Specific immunity develops in about 10 to 12 weeks, and further spread of the organism is prevented. Within 2 to 12 weeks the purified protein derivative (PPD) skin test/interferon-γ release assays becomes positive, but infection may remain asymptomatic for several years (latent TB infection or LTBI) or progress to active TB.

Within 2 years of the initial infection approximately 5 percent of persons develop active TB because of a failure of the immune system to control the mycobacteria. If no disease develops within this 2-year

period, the patient continues to have a low annual risk of reactivation. In general, the remaining risk is about 5 to 10 percent (for a total lifetime risk of about 10 to 15 percent).[11]

Persons at risk of TB infection include those who have close contact with pulmonary or laryngeal TB cases (in contact for days or weeks), foreign-born persons (within 5 years of arrival to the United States), residents and employees in crowded settings, healthcare personnel (HCP), some underserved/low-income populations, and infants exposed to high-risk adults. [10]

Persons with LTBI at increased risk of progressing to active TB include persons with HIV; persons with PPD conversion within the past 2 years; individuals with silicosis, diabetes mellitus, chronic renal failure/end stage renal disease, hematological malignancies, cancer, or those with 10 percent below ideal body weight; persons receiving immunosuppressive treatments or organ transplant; patients with a history of intestinal bypass or gastrectomy; people with chest radiograph (CXR) consistent with prior TB; and individuals with history of crack cocaine, alcohol, tobacco, and injection-drug use.[10]Diabetes mellitus may be of particular concern given its increasing prevalence in the U.S. population.[14]

Source patients at increased risk of TB transmission include those with cough, cavitations on CXR, positive smears, laryngeal or pulmonary TB involvement, failure to cover mouth when coughing, inappropriate use of TB medications, and those that undergo aerosol-generating procedures such as bronchoscopy (see Table 95-1).[12,13,15,16]In addition, environmental factors such as TB exposures in closed spaces, inadequate ventilation, air recirculation, poor management of specimens, and inadequate cleaning of reusable medical equipment may contribute to transmission.[10,13,17]

CLINICAL FEATURES

Clinical features of TB are variable. Before the beginning of the HIV epidemic, about 85 percent of TB cases were limited to the lungs and 15 percent had either extrapulmonary or both pulmonary and extrapulmonary involvement (this can vary depending on the race, ethnicity, age, comorbidities, genotype of MTB strain, and patient immune status).[18,19]Patients with HIV tend to have more atypical presentations, with extrapulmonary compromise occurring in 62 percent of cases. Clinical presentation is variable in HIV-positive patients; patients with CD4 T-cell count of less than 75 may present with disseminated disease, with absent pulmonary symptoms, and a clinical course characterized by chronic fevers, widespread organ involvement, and early mortality.[18]The presence of cough, fevers, night sweats, or weight loss has a sensitivity of 80 percent to detect cases where additional testing to rule out active TB is indicated.[20]

Table 95-1 Clinical and Environmental Factors Associated with Increased Risk of TB Transmission

Increased Risk of TB Transmission[8]
Characteristics of patients with TB that increase risk of transmission

Sputum/aerosol-producing activities	Studies in the 1960s showed that contacts of individuals that higher cough frequency (greater than 48 times per night) were more likely to have TST conversion. It was also noted that speaking loudly for 5 minutes produced a similar number of infectious particles as a cough. Singing and coughing may be similarly infectious.[13]
Positive AFB smear results	Smear positivity correlates with transmission. Studies performed between 1930 and 1971 showed that close contacts have a 29 to 79 percent chance of having a positive PPD. Household contacts of smear-positive TB cases have a 30 to 50 percent higher rate compared to individuals in their community. Reactivity among smear-negative contacts is 0 to 8 percent.[13,16]
Laryngeal or pulmonary TB cavitation on chest x-rays	Laryngeal TB is highly infectious. Transmission has been documented after very short periods of exposure. This was initially reported in guinea pigs and later in human outbreaks.[12] Patients with cavitary TB are more likely to have persistently positive AFB in the sputum after induction therapy.[18,19]
Inappropriate cough etiquette, respiratory hygiene	Although solid data are lacking, covering the mouth when coughing may lead to decreased aerosolization of infectious particles.
Inappropriate anti-TB treatment	Drug-resistant TB can lead to delays in diagnosis and institution of appropriate therapy, prolonged infectivity, and transmission. This has been well documented among patients with MDR-TB and HIV coinfection. XDR-TB has been associated with very high mortality among HIV patients in developing countries.[15]
Cough-inducing or aerosol-generating procedures	Duration of exposure correlates with infection, and use of cough-generating procedures has been found to further contribute to this. In an outbreak of TB, exposure to patients undergoing respiratory manipulation through mechanical ventilation in an emergency department resulted in TST conversion among 14 percent (16/112) of exposed HCP after only 4 hours of exposure. In addition, a high rate of TST conversion has been reported when respiratory procedures were performed in areas with inappropriate ventilation.[13,17]
M. tuberculosis strain	Some strains have been associated with increased infectiousness. For example, one single strain caused 10 percent of TB infections from 1991 to 1994 in New York City[13]
Environmental factors that facilitate TB transmission	
TB exposure in enclosed/small spaces, inadequate ventilation, recirculation of air	Several outbreaks have been associated with recirculated air. These included not only healthcare settings, but also naval ships, school buses, classrooms, and bars.[13,17,20] Equally important is duration of exposure. Previous studies in patients exposed to a school bus driver described this correlation: the longer the child was on the bus, the more likely he or she was to have positive TST.[13]
Inadequate disinfection of medical equipment	Transmission of TB has been associated with inadequate disinfection of bronchoscopes. Bronchoscopy has also been associated with transmission of TB through aerosolization.[17]
Improper handling of specimens	TB has been transmitted through punctures (i.e., prosector's warts).[13]

Primary TB infection is usually asymptomatic, with a few patients developing fevers, cough, or erythema nodosum. Patients with advanced HIV disease can develop progressive dissemination during primary infection. Radiological presentation can be variable, but the classic Gohn complex (includes a primary focus of infection, or infiltrate and lymphadenopathy on draining lymph nodes) or, in progressive cases, a miliary pattern can be reported. Dissemination during this primary TB infection can be controlled by

the immune system, but multiple nonpulmonary sites of controlled infection can be established and can lead to extrapulmonary disease during postprimary TB reactivation.[18,19,21]

Postprimary TB usually manifests with productive cough, fevers (37 to 80 percent), and night sweats. It is characterized by infiltrates located on the upper lobes or the superior segments of the lower lobes, and is frequently associated with cavitation on chest x-rays. Respiratory symptoms usually last more than 2 to 3 weeks (this is particularly useful to help differentiate from other respiratory illnesses like influenza), and cough may initially be nonproductive but subsequently followed by sputum production as tissue necrosis progresses. Pulmonary TB can be associated with hemoptysis (may be small amounts if secondary to superficial erosion of airway, or massive amounts if it is the result of rupture of a dilated vessel on the pulmonary cavity, known as a Rasmussen aneurysm), weight loss, chest pain, anorexia, malaise, and debilitation.[22,23]Patients with HIV and higher CD4 T-cell counts may have the typical apical infiltrates of postprimary TB. In patients with HIV and low CD4 cell counts, the presentation of pulmonary TB may be atypical with a military pattern, lower lobe infiltrates, or even normal chest x-rays.

Extrapulmonary TB may be associated with different symptoms based on the organ of involvement. TB lymphadenitis usually presents with painless cervical or supraclavicular lymphadenopathy. Disease can progress, developing overlying erythema and eventually sinus tracts. Pleural involvement is characterized by pleuritic chest pain, sometimes without apparent lung parenchymal involvement. Pleural TB may be paucibacillary but occasionally can manifest as empyema. TB meningitis is usually caused by reactivation of MTB or dissemination. It usually involves the base of the brain, and cranial nerve involvement, headaches, and decreased level of consciousness of variable duration (days to weeks) are characteristic. Diagnosis is usually made through lumbar puncture, where a lymphocytic pleocytosis with low glucose and high protein is observed. AFB stain of the cerebrospinal fluid (CSF) requires a large volume sample (usually > 6 mL), but yield is modest. Culture is required for confirmation. Less commonly, TB may present with a focal lesion (tuberculoma) and focal neurological deficits.[19]

TB can involve the spine (Pott disease, usually involving the thoracic spine but possibly involving any level of the spine), it is slowly progressive over weeks to months or even years, and can lead to spinal deformity and, eventually, spinal instability. Involvement of other bones and joints is possible, and the most common manifestation is swelling and pain. Biopsy is required to confirm the diagnosis.[19]

Genitourinary (GU) TB has been associated with sterile pyuria. All levels of the GU tract can be involved, and in males TB can manifest as prostatitis, orchitis, or epididymitis. Clinical features may be subtle and sometimes extensive damage to the GU tract is present before diagnosis is confirmed. In females involvement of the genital tract is more common, with menstrual irregularities, pelvic pain, and infertility being common complaints. Diagnosis is usually obtained through AFB cultures of the urine or tissue biopsy. Pulmonary involvement in patients with GU TB is not uncommon.[19]

Peritoneal involvement in TB may present as ascites, abdominal pain, and weight loss (usually with lymphocytic pleocytosis) and requires peritoneal biopsy and AFB stain for confirmation. Yield of AFB stains in peritoneal fluid is low. If adenosine aminhydrolase is elevated in the peritoneal fluid it may be helpful. Involvement of the gastrointestinal (GI) tract usually occurs proximal to the terminal ileus, but involvement of any area of the GI tract from mouth to anus has been reported. Terminal ileum and cecum are most common sites of GI/abdominal involvement in TB, and clinical manifestations such as pain and obstruction (with or without a mass), ulcerations, and fistulas/fissures are not uncommon.[19]

Pericardial TB may present with fevers, weight loss, and pain, and later with hemodynamic compromise. Dyspnea, orthopnea, and lower extremity edema occur later in the disease course. Pain usually changes with position. Diagnosis usually requires aspiration of pericardial fluid and pericardial biopsy.[19]

LABORATORY DIAGNOSIS/PROCEDURES

Active Tuberculosis

Microbiological Diagnosis

The definitive diagnosis of active TB depends on the identification of MTB in specimens from the patient. Patients with suspected TB who are admitted to the hospital should be placed in appropriate airborne infectious isolation (AII), as discussed under Infection Prevention Measures.

Because pulmonary disease is the most common form of TB, patients with suspected TB should have a CXR. If the radiograph is abnormal, or if the patient has respiratory complaints, sputum specimens should be collected for AFB staining and culture or other direct tests. AFB staining and culture of sputum should be obtained three times, at least 8 hours apart, and cultures should be performed on liquid media.[10,18]Having three negative sputum smears is recommended in order to discontinue respiratory isolation.[24]Automatic liquid media systems can help decrease time to positivity (i.e., microbacteria growth indicator tube). In resource limited settings, solid culture media are frequently employed.[18]

If the patient is not producing sputum, respiratory therapists who have been appropriately trained can use nebulized hypertonic saline to induce sputum for laboratory testing. Gastric washings can be used in pediatric patients, as small children often swallow their secretions rather than expectorate.

If sputum specimens are negative for AFB on staining and the diagnosis is uncertain, the patient may need to undergo bronchoscopy with bronchoalveolar lavage (BAL) and perhaps biopsy to obtain additional specimens.

If extrapulmonary disease is suspected, the involved tissue biopsy or fluid should be submitted to the laboratory for testing. In this case, the tissue should be submitted for mycobacterial culture and/or other testing with a portion sent for histopathological preparation with special stains for AFB.

MTB can be cultured in special broth media or on solid media. Although traditionally considered to be slow growing, use of modern broth culture methods allows the organism to be recovered in as little as a few days. Likewise, species identification, which has traditionally required slow biochemical tests, has been improved with the introduction of molecular biological techniques. Deoxyribonucleic acid (DNA) probe and polymerase chain reaction (PCR)-based technologies can often provide definitive species identification on the same day that growth of the organism has been confirmed. Two nucleic acid amplification tests (NAA test) have been approved by the U.S. Food and Drug Administration (FDA) to identify MTB in respiratory specimens even before a specimen smear is AFB positive.[25]These tests allow rapid identification of MTB, but an AFB culture is still required for definitive diagnosis. Additionally, an isolated positive NAA test in a patient with a low clinical suspicion for TB cannot be used to confirm diagnosis.[25]

WHO recommends a first-line molecular diagnostic test that simultaneously detects TB in sputum and evaluates for rifampin resistance. It is a self-contained, automatic cartridge-based nucleic analysis system that can identify targeted nucleic acid sequences. The rifampin resistance is amenable to testing because 95 percent of resistant isolates have mutations on the *rpoB*gene, which encodes the active site of the bacterial RNA polymerase. The sensitivity of the assay is two orders of magnitude better than sputum microscopy—as good as solid culture media but slightly lower than liquid culture media. This test has been validated in large clinical trials performed in resource-limited settings. The sensitivity of the test is around 90.4 percent and the specificity is 98.4 percent. The sensitivity of the assay is slightly lower for HIV-positive patients with pulmonary TB. The test has been mostly studied for the diagnosis of pulmonary TB; in the future, as more data become available, use in extrapulmonary sites may be possible.[26]

Susceptibility

Although DNA technologies are extremely helpful in speeding the diagnosis of TB, cultures will still be required for the foreseeable future because identification of antimicrobial sensitivities requires growth of the organism. Susceptibility testing should be done on an initial isolate from every patient with newly diagnosed TB. Likewise, susceptibility testing should be done if the patient remains culture positive after 3 months of treatment.[20]Globally, MDR-TB has increasingly become a problem.[1]About 310,000 cases of MDR-TB were reported in 2011. Most of these cases were reported from China, India, Russian, Pakistan, and South Africa. Furthermore, XDR-TB was identified in the United States in 1993. The annual number of cases has decreased from 18 in 1993 to two in 1997.[27]In 2008, there were five cases; in 2009, zero cases; in 2010, one case; and in 2011, six cases.[9]Patients with XDR-TB have a high mortality rate. In a study from Africa, mean time to death after diagnosis was 16 days.[28]

There are several possible techniques that may be used for TB susceptibility testing. The most widespread is the agar proportion method on Löwenstein-Jensen agar and Middlebrook 7H11 agar. However, the accuracy of this method to evaluate resistance to second line drugs is less well established. Rifampin resistance can be detected within 2 hours. The microscopic observation drug susceptibility assay (MODS) uses a liquid culture media to observe microscopic growth of MTB and evaluate drug resistance.[28]

Clinical Diagnosis

Although actual growth of MTB from patient specimens is required for the definitive diagnosis of TB, a presumptive diagnosis may be made on clinical grounds. Patients who present with an appropriate clinical history and characteristic CXR findings (e.g., upper lobe infiltrates) may be started on appropriate therapy (see section on therapy of active disease) while sputum specimens are being obtained.

If a patient is thought to have TB, even if the sputum or tissue specimens are AFB smear-negative, anti-TB drug therapy should be continued empirically. Even if the organism fails to grow, a clinical response to anti-TB therapy is sufficient to make a presumptive diagnosis of TB and finish a full course of treatment. Likewise, the presence of caseating granulomas on tissue biopsy or the presence of lymphocytic pleocytosis and hypoglycorrhachia in the spinal fluid may be sufficient, along with the

patient's clinical presentation, to commit the patient to a full course of anti-TB therapy, even if the organism does not grow.[29]

Latent Tuberculosis Infection

Screening and treatment of LTBI is recommended for groups with high prevalence of LTBI and/or those at risk for TB exposure/disease. Two methods of screening are currently recommended: TST or interferon gamma release assays (IGRA).[30]

Tuberculin Skin Test

TST involves injection of purified protein derived from the mycobacterial cell wall. The test relies on the fact that persons who have been infected with TB will have a delayed-type hypersensitivity reaction to this reagent. The TST is a screening tool to detect people with LTBI; it cannot be used for ruling in or ruling out active TB. This is because a positive TST merely indicates a history of LTBI at some time in the past—it conveys no information regarding the current status of the person's infection (which may even have been cured previously). Likewise, a negative test does not rule out active TB because people with active TB may well have a negative TST even in the presence of positive controls. (It is for this reason that control testing is no longer recommended—it adds no clinically useful information.[30]) In fact, up to 20 percent of persons with active TB will have negative TST results.

Candidates for Screening

TST should be done for those at risk for acquiring TB so that treatment of LTBI can be instituted to prevent the development of active disease. HCP, employees and inmates of prisons, nursing home residents and employees, foreign-born persons from areas with high endemic rates of TB, intravenous (IV) drug users, homeless persons, residents of inner city neighborhoods, and patients with HIV, end-stage renal disease, diabetes, or other immunosuppressing diseases should be tested. People exposed to a patient with active TB should also be tested. Pregnancy is not a contraindication for TST.[10]

Mantoux Test

The preferred way to perform TST is by the Mantoux method.[8,10] A tuberculin syringe is used to inject 5 tuberculin units (5 TU—usually 0.1 mL) of PPD intradermally. The test is generally placed on the volar (palmar) surface of the forearm, but it may be placed on the dorsal surface if necessary. A properly placed test raises a small wheal at the site of injection.

The TST is read 48 to 72 hours after placement. A positive test is determined by the number of millimeters of induration (not erythema) caused by the reaction to the tuberculin. Different cut points are used depending on the likelihood of the individual having a TB infection and on the likelihood of progressing to active TB if infection is present. Criteria for TST interpretation developed by the CDC and the American Thoracic Society (ATS)[10,31,32] are listed in Table 95-2. It is important to note the actual number of millimeters of induration when recording a TST result, and not just negative or positive, because new information about the patient may change the interpretation of the test. In addition, for persons receiving serial TSTs the exact size is important in interpretation of subsequent tests. A test is

considered a conversion (i.e., a change from negative to positive) if there is an increase in the amount of induration by 10 mm compared with the previous test.[31]

Table 95-2. Criteria for Positive Mantoux Tuberculin Test Reactions[31]

Table 95-2 Criteria for Positive Mantoux Tuberculin Test Reactions

Induration Size (mm) For Positive Test	Group
≥5 mm	HIV-positive persons Recent contacts of TB case Fibrotic changes on CXR consistent with old TB Patients with organ transplants and other immunosuppressed patients (≥ 15 mg/day prednisone for 1 month)
10mm	Recent arrivals (< 5 years) from high-prevalence countries Injection drug users (HIV-negative) Residents and employees of high-risk congregate settings: healthcare facilities, prisons, shelters, etc. Mycobacteriology lab personnel Persons with high-risk clinical conditions (e.g., chronic renal failure, silicosis, gastrectomy, malnutrition) Medically underserved high-risk minorities Children < 4 years of age or infants and children exposed to adults in high-risk categories
≥15 mm	Persons with no risk factors for TB

Interferon Gamma Release Assays

In 2001 the FDA approved the first IGRA, but it was less specific than the TST. More recently, new IGRAs that are more specific have been developed. They evaluate the release of interferon gamma from the host cell when exposed to TB proteins such as the early secretory antigenic target 6 (ESAT-6) and the culture filtrate protein 10 (CFP-10). These proteins are present on MTB organisms but absent from BCG strains, and most nontuberculous mycobacterium, increasing the specificity of the test (these antigens are present on *M. marinum*, *M. kansasii,*and *M. szulgai*). In 2007 a test was approved allowed for the antigens to be in contact with blood in special tubes. After an incubation period of about 12 to 16 hours, the plasma is separated and interferon gamma can be measured. Specificity of this test is high, around 99 percent.[30]

Finally, in July 2008, a test was approved by the FDA that used an enzyme-linked immunospot assay is used to measure the number of cells that secrete interferon gamma (spots at each test well). Specificity is around 88 percent.[30]

TST and IGRAs can both be used to diagnose latent TB infection. Both groups of tests have limitations. TST may be better to detect remote exposures, but IGRAs can be more specific. There is some individual variations on interferon gamma release in individuals, so occasional reversion or conversion of IGRAs have been reported on serially tested individual patients.[33]TST is preferred in children under 5 years of age, as more data are available for TST than for IGRAs in this population. IGRAs may be preferred in patients with a history of bacillus Calmette–Guérin (BCG) therapy for bladder cancer or vaccination and on those unlikely to return for reading if TST is administered.[30]

Whereas the sensitivity of QFT-G for detecting MTB infection in persons with untreated, culture-confirmed TB is approximately 80 percent in published studies,[34,35]its sensitivity for particular groups of TB patients (e.g., young children and immunocompromised patients) has not been determined. The agreement between QFT-G and TST results in persons at increased risk for LTBI facilitated approval and acceptance of TST.[30]

QFT-G can be used in all circumstances in which the TST is used, including contact investigations, evaluation of recent immigrants who have had BCG vaccination, and TB screening of HCP and others undergoing serial evaluation for MTB infection. QFT-G usually can be used in place of (and not in addition to) the TST.[30,36,37]

TREATMENT

Therapy of Active Disease

Initial therapy for active TB will always need to be started before antimicrobial sensitivities are known and, frequently, even before the organism itself has been cultured. Appropriate treatment of TB should include at least two drugs to which the organism is sensitive to prevent the development of resistance. Comprehensive treatment recommendations for TB have been provided by the ATS, CDC, and the Infectious Diseases Society of America.[38]

To ensure that at least two effective drugs are being given, patients are typically started on four-drug therapy with INH, rifampin (RIF), pyrazinamide (PZA), and ethambutol (EMB). If there is a high likelihood that the patient has TB that is resistant to more than one drug, more than four drugs may need to be given initially. This should be done in consultation with someone experienced in treating MDR-TB. If XDR-TB is suspected, specialist care is essential. In some circumstances (e.g., pregnancy or severe liver disease), the typical initial regimen must be altered; this, too, should be done by someone experienced in treating TB. The final drug regimen can be determined once sensitivities are known.

Directly observed therapy (DOT) should be considered the standard of care for all patients, regardless of the individual's clinical or social status.[39]TB treatment regimens require taking multiple drugs consistently for a long period of time. Failure to take the drugs appropriately may lead to the development of MDR-TB and almost certainly to treatment failure. Compliance with multiple self-administered drugs (prescribed for any reason) is very poor, and HCP cannot reliably predict who will or will not be compliant. With DOT, HCP deliver the medication and watch the patient take the pills. DOT allows for the option of doses being given less frequently than daily. Patient self-administered therapy should be taken daily to minimize the impact of the occasional missed dose.

Typically, after a 2-month initial phase, a continuation phase using fewer drugs can be used once sensitivities are known. The total duration of therapy is typically 6 months but may be longer, depending

on circumstances. Patients with extrapulmonary TB are generally treated the same as patients with pulmonary disease, though MTB meningitis and bone and joint disease are often treated for 9 to 12 months. Patients with pulmonary cavities that remain culture positive after 2 months of appropriate therapy usually require extension of the maintenance phase with INH and RIF from 4 to 7 months (total of 9 months of therapy) due to the high failure rate (around 22 percent) with a 6-month course of therapy.[38]

All patients should have at least monthly sputum samples collected for stain and culture to document clearing of the infection. Patients who do not respond appropriately should be referred to someone experienced in the treatment of TB. Two or more drugs should be added to a failing regimen (never one agent alone given risk of developing resistance).[38]

Patients started on therapy should have a baseline aspartate aminotransferase (AST), visual acuity, and color vision check. While on therapy, patients should be monitored clinically for drug toxicity; hepatotoxicity (liver) is the most common adverse reaction. Although most often caused by INH, hepatotoxicity may also be caused by RIF and PZA. EMB has ocular (eye) toxicity. Pyridoxine (vitamin B6) supplements should be considered in patients on INH to reduce the risk of peripheral neuropathy (see section on INH in the treatment of LTBI).

TREATMENT OF LATENT TUBERCULOSIS INFECTION

All persons found to have a positive TST or IGRA (as discussed) should be evaluated for the presence of active TB. This evaluation should include questions about possible exposures to TB, a review of symptoms that might be suggestive of TB (e.g., fever, night sweats, weight loss, or cough lasting more than 2 weeks), a lung exam, and CXR. Patients with a suggestive CXR (e.g., an upper lobe or cavitary infiltrate) or suggestive symptoms should have three sputum specimens collected for AFB stain and culture. Treatment of LTBI should be withheld in such patients until cultures are negative to prevent the possibility of treating active TB with only a single drug. If there is a strong suspicion of active TB, four-drug therapy should be started (see Therapy of Active Disease).

Because of the relatively high risk of developing TB within 2 years of the initial exposure, all persons who have had a negative skin test within the previous 2 years and who now have a positive test (recent converters) should be treated for LTBI, regardless of age. Likewise, in patients who are at risk for TB (including, but not limited to, patients with HIV, patients on steroids or other immunosuppressive drugs, recent contacts of patients with active TB, patients with diabetes mellitus, patients with end-stage renal disease, and immigrants from areas with high endemic rates of TB who have been in the United States less than 5 years), a positive TST is generally considered an indication for treatment even if the TST is not a recent conversion.[31]

In general, any patient with LTBI should be considered for preventive therapy.

Isoniazid

INH, 5 mg/kg (up to 300 mg) as a daily oral dose, is the drug of choice for treatment of LTBI. The most recent recommendations are for 9 months of therapy with INH for children and adults, including adults with HIV.[31,40]

Drug-induced hepatitis is the most concerning potential side effect of INH. The incidence increases with age, from essentially 0 percent in those under 20 years of age to 2 to 3 percent in those over 50. Excessive ethanol ingestion increases the risk of hepatic toxicity. Nonalcoholic liver disease may also

increase the risk, though this is less clear. Patients taking INH should be monitored for symptoms of hepatitis (malaise, nausea/vomiting, abdominal pain, jaundice, and scleral icterus) at least monthly. If monthly follow-up is not possible, INH should not be prescribed. Monthly screening of serum transaminases (liver enzyme tests, including AST and alanine aminotransferase [ALT]) can be considered but is expensive, compliance can be difficult, and it is not recommended as a routine measure. AST or ALT should be checked in any patient who reports symptoms that may be attributable to drug-induced hepatitis; the INH doses should be held pending results of the test. INH therapy should be stopped in any symptomatic patient with a transaminase level more than three times the upper limit of normal and in any asymptomatic patient with a transaminase level more than five times the upper limit of normal. Patients with a less-significant elevation should be followed closely with serial enzyme evaluations. Hepatic toxicity is usually completely reversible if the drug is stopped promptly, but fatal cases of INH-induced hepatitis have been reported.

Pyridoxine (vitamin B6) clearance is increased in patients taking INH. Pyridoxine deficiency can lead to peripheral neuropathy, with initial manifestations of numbness and tingling in the hands and feet. Pyridoxine should be given to all patients with poor nutrition or at increased risk for developing peripheral neuropathy (e.g., alcoholics, diabetic patients, pregnant women) at a dose of 50 mg taken orally every day. Consideration should be given to giving pyridoxine to all patients on INH.

Rifampin for the Treatment of LTBI

In patients with a positive TST who warrant treatment of LTBI but who cannot take INH, and in those whose positive skin test has a high likelihood of being caused by INH-resistant MTB (e.g., recent converters after an exposure to a patient with INH-resistant TB), RIF 10 mg/kg (max 600 mg) in a daily oral dose can be given for 4 months. If the patient is taking other medications that may interact with RIF, or if the patient wears soft contact lenses that will be stained by RIF in the tears and is not at very high risk for the development of active TB, then withholding therapy and monitoring for signs or symptoms of active TB is an acceptable alternative. Recent studies suggest that overall adverse drug events are less common with a 4-month RIF regimen.[41]This, combined with the significantly shorter duration of therapy, may lead to higher overall rates of compliance. This is an area of active investigation.

Rifapentine and INH for Treatment of LTBI

Therapy for LTBI with 9 months of INH is difficult given prolonged duration of therapy. The rate of completion of INH therapy may be as low as 60 percent. More recently, the combination of rifapentine and INH weekly for 12 weeks has been proposed as an alternative to INH. Benefits observed are a higher rate of completion of therapy and shorter duration of therapy with a minimal increase in adverse events.[42]Disadvantages include the recommendation to administer as DOT and the slightly higher rate of adverse events in the combination group.

The INH/rifapentine combination is recommended in individuals who are at least 12 years of age and are at risk for developing active TB (such as exposure to active TB, recent TST or IGRA conversion, or radiological findings of healed TB). The choice between the combination regimen and the INH monotherapy should be based also on the feasibility of DOT implementation and the individual social and medical situation of the patient.[43]

Other Regimens to Avoid and Management of LTBI in Contacts with MDR-TB

At one time a 2-month regimen of RIF plus PZA was considered an acceptable alternative therapy for LTBI when INH could not be used. However, this regimen is no longer recommended because of high rates of drug-induced hepatitis (sometimes fatal) and should only be considered under unusual circumstances.[44]

For persons who have converted their skin tests after exposure to patients with MDR-TB, consideration can be given to using multiple drugs to which the organism was sensitive or forgoing treatment of LTBI and monitoring the patient for evidence of active TB. This decision should involve both the patient and a physician experienced in dealing with MDR-TB.

Bacille Calmette-Guérin Vaccination

BCG is an attenuated strain of *M. bovis*that is given as a live bacterial vaccine to prevent the development of active TB. Studies of BCG have shown a wide range of effectiveness, from 0 to 80 percent.[45,46,47,48]Part of the difficulty in interpreting any of these studies is that there is no standard preparation of BCG. Nevertheless, in areas where TB is highly endemic, BCG vaccination is probably an effective strategy in reducing severe cases of TB, especially in children.

BCG vaccination may induce an induration on a TST, the degree to which it does wanes with time. Current recommendations in the United States are to interpret TST results without considering BCG vaccination status, because a positive test is much more likely to represent latent TB than to represent an unusually strong BCG reaction.[49]

BCG is not recommended in most HCP in the United States given its unproven efficacy to prevent TB in adults.[50]BCG is recommended for those who are continuously exposed to patients with active MDR-TB in settings where transmission to HCP is likely and comprehensive control measures have not been successful. Because it is a live vaccine, BCG should not be given to HIV-infected or otherwise severely immunocompromised persons.

INFECTION PREVENTION MEASURES

Tuberculosis Prevention in Healthcare Settings

TB remains a safety challenge for healthcare systems in the United States. In the recent past, there were multiple reports of patients who acquired the infection while receiving medical care.[51,52,53]This is partly due to the complexity of the diagnosis, atypical presentations, and, perhaps, the perception that TB is a problem of the past—as the disease became less prevalent over the past 15 years.[52,54,55,56,57]In addition, it is difficult to trace unsuspected exposures in healthcare settings, and screening methods like TST may not always be useful.[10,58]Many clinicians may not have frequently treated TB given its declining prevalence, and some specialties are less likely to make an early diagnosis of TB, leading to delays in airborne isolation.[52,56]Furthermore, it seems like TB transmission in healthcare settings frequently goes undetected. In some low prevalence countries, TB is only suspected by epidemiological links in about 25 percent of the cases.[58]HCP tend to be frequently affected. Also, patients that are part of clusters tend to have more pulmonary disease and cavitary disease, which have been shown to be associated with increased risk of transmission.[10,58]

Early detection and diagnosis of TB and LTBI may be challenging when testing foreign-born HCP due to misperceptions regarding TST interpretation in the setting of remote BCG vaccination and perceived low risk of active TB.[59]Failure to detect or prevent active TB has led to extensive contact investigations and transmission to patients. Availability of more specific tests to diagnose LTBI, like interferon release assays, may help reduce the concerns about false-positive PPD tests in HCP with prior BCG vaccination.[59,60]

Although interferon gamma release assays are more specific, they tend to be more expensive and can still have occasional false-positive results. as some organisms like *M. kansasii*, *M. szulgai,*and *M. marinum*can have ESAT-6 and CFP-10, which induce release of interferon measured by these assays.[59]

Currently, they can be used in the same settings as TST, but they share limitations, including the fact that they measure an immunological response, which may lead to false negatives among immunosuppressed patients.[60]

The dynamics of TB transmission in hospital settings are complex. Although pulmonary TB is most commonly implicated in outbreaks, extrapulmonary and disseminated TB have been shown to lead to potential clusters of transmission. D'Agata et al. reported a case of disseminated TB that manifested as fever and testicular pain and was found to have an associated prostatic abscess, requiring orchiectomy and packing of the wound and twice a day irrigation. The patient's radiographs were originally normal and, as his condition deteriorated, showed only interstitial infiltrates that improved with diuresis. The patient underwent BAL, and cultures were negative for AFB (no biopsies were taken). The patient died, and disseminated TB with caseating granulomas was noted in several tissues, including the lungs. At that facility, the rate of PPD conversion was 0.2 percent. Among the providers in contact with the patient after the surgery (nurses, students, and pathology personnel), 12/95 (13 percent) had a PPD conversion to more than 10 mm. The major risk factor for PPD conversion was packing of the wound.[53]

Failure to isolate patients with active TB is not uncommon in North America. In Canada, Greenaway et al. evaluated the management of TB patients including 429 patients admitted to 17 hospitals over a 3-year period. They found that TB diagnoses were initially missed in 45 percent of cases, and even after 1 week, 30 percent of the patients were still not properly treated.[57]They found that atypical manifestations and absence of cough were associated with delayed diagnosis. They further classified hospitals among those with low, moderate, and high admission rates of TB patients; the ones with higher rate of admission were less likely to delay isolation. Hospitals with lower rate of TB patient admission were also most likely to get TST conversion, even after adjusting for other factors.[57]

Several interventions to prevent and control the spread of TB have been proposed.[61]Since 1889 the New York City Department of Health recommended a comprehensive management program including surveillance, public education, isolation of infectious patients, and free laboratory testing of patients. This program expanded and eventually suffered from its own success. In 1988, only eight of the original 24 TB clinics remained. The diminished public health efforts to control TB and the HIV epidemic resulted in a cure rate of more than 50 percent of patients with TB by 1989, higher proportions of resistance, and high rates of relapse. Outbreaks of TB became common in hospitals.[61]However, in 1992 several interventions were implemented, including reinstitution of DOT (proportion of completion of therapy increased to 90 percent), intense case management, and (in only about 1 percent of cases) involuntary detention. Individual housing was provided to homeless persons (instead of large communal dormitories), and practices to screen, isolate, and follow up with incarcerated individuals with TB were

implemented. Treatment regimens were expanded to include four medications in about 89 percent of cases.[61]This led to a significant decrease in the incidence of TB as early as 1994.[61]

In 2005, the CDC recommended a multilevel intervention strategy to prevent healthcare-associated TB transmission, and in 2009 the WHO published similar recommendations (see Table 95-3).[10,62]The intervention strategies included implementation of administrative, environmental, and respiratory protection controls.[10,62]The effectiveness of these protective intervention strategies is dependent on HCP recognizing and isolating patients with pulmonary TB. A deviation from the CDC protocols due to the delay in identifying and diagnosing TB or placing patients with suspected TB under appropriate isolation precautions has been associated with an increased rate of TST conversion (marker of TB infection).[63] This has been described in multiple healthcare-associated outbreak investigations.[64,65,66,67,68,69]Failure to follow isolation precaution guidelines places not only other patients but also HCP at high risk of developing active TB.[65]Furthermore, TB-infected HCP can lead to TB transmission to coworkers, patients, and visitors,[59]which has serious implications for patient safety. This has been described in outpatient and inpatient settings, adult and children populations, and hemodialysis centers.[70,71,72,73,74]TB exposure investigation and postexposure follow-up can be difficult. In Atlanta, an extensive investigation of healthcare-associated transmission of TB identified eight HCP who developed active pulmonary TB and subsequently exposed 586 patients. Facility and county health department personnel were able to contact 34 percent of those exposed to complete an appropriate evaluation. Approximately 72 percent of the patients were lost to follow-up, many of whom were homeless and HIV positive and were at high risk of developing active TB.[74]Possible infection prevention and control measures that could have prevented the outbreak include timely detection of TB in both patients and HCP, prompt initiation of Airborne Precautions for suspected TB cases (i.e., placement of patients in negative pressure rooms and use of N95 respirators by HCP), initiation of appropriate anti-TB therapy, adherence to guidelines for discontinuing isolation, and annual training and TB testing for HCP.[10]

Table 95-3 CDC and WHO Recommendations for Preventing TB Transmission in Healthcare Settings

CDC[10]	WHO[76]

Administrative controls	• Assign responsibility for TB infection control • Conducting TB risk assessment • Disseminate written TB infection control plan to detect, isolate (airborne), and treat suspected or confirmed TB cases • Timely availability, testing, and reporting of testing to infection control and ordering provider • Effective practices for management of suspected or confirmed TB cases • Proper cleaning and disinfection of contaminated equipment • Train HCP on TB prevention, transmission, and symptoms • Screening and management program of HCP at risk for, with, or exposed to TB • Use epidemiology-based prevention principles such as using setting related infection data • Use signs advising proper infection control practices (i.e., respiratory hygiene and cough etiquette) • Coordinate with local or state health department efforts to control TB	• Develop facility plan for TB control, promote local coordinating bodies for TB prevention/control • Optimize use of available spaces and consider renovation or additional construction to optimize implementation of controls • On-site surveillance of TB among HCP; assess the facility • Advocacy, communication, and social mobilization for patients, HCP, and visitors • Evaluate and monitor TB control measures • Participate in research • Triage, separation of TB patients, infection control strategies (cough etiquette/respiratory hygiene), and decrease time in healthcare facility • Prevention of HIV for HCP, ART for those who are positive, and LTBI and TB treatment • Rapid testing, shorter turnaround time of testing, parallel rather than sequential investigation of cases and use of algorithms
Environmental controls/ personal protective equipment	• Develop and implement a respiratory protection program • Train HCP on respiratory protection and patients on respiratory hygiene and cough etiquette • Use and availability of negative-pressure rooms based on risk assessment (ongoing monitoring of negative-pressure ventilation rooms) • UV light may be used in addition to appropriate ventilation	• Use of respirators • Ventilator systems: ideally 12 air exchanges per hour • UV light irradiation when appropriate/ventilation not available
Additional comments	Infection prevention interventions are based on predefined risk assessments, which place settings in one of three categories: low risk, medium risk, or ongoing transmission. Need for HCP PPD screening is defined based on these categories.	Includes elements of TB prevention not only in the healthcare setting but also at the national and subnational levels.

Despite the widespread implementation of effective and evidence-based interventions (like the CDC and WHO guidelines to prevent TB), TB exposure continues to occur in U.S. healthcare settings, and additional research has been initiated to evaluate the causes of the failure of the proposed controls, in particular in regions where TB continue to be more prevalent.[10,62]

Tuberculosis Control Plan

The rise of TB in the United States in the late 1980s and early 1990s, with several documented hospital outbreaks of active TB and TST conversions, led to a renewed appreciation for the need for aggressive measures to control TB in healthcare institutions. In 1994, the CDC published extensive guidelines on

what should be considered when developing a TB control plan.[75] The CDC revised the guidelines in 2005 to include recommendations for laboratories and additional outpatient and nontraditional healthcare settings. These guidelines include expanded measures aimed at reducing incidence of TB and eliminating TB transmission from undiagnosed patients to HCP.[10]

Control measures should be undertaken for patients who are likely to be contagious. Patients with pulmonary or laryngeal disease (or suspected disease) are considered contagious. Most patients with extrapulmonary TB are not contagious because the organism is not aerosolized. Exceptions occur when a mechanism for aerosolizing the MTB organisms is provided. For instance, HCP have been infected by irrigating cutaneous wounds caused by MTB, as well as during the performance of autopsies on patients with extrapulmonary TB.[78–80]

Risk Assessment

The first step in developing a TB control plan is to assess the institution's TB risk. This depends on both the prevalence of recognized and unrecognized TB patients in the healthcare facility and in the surrounding community, as well as on patterns of TST conversions or positive blood assay for *M. tuberculosis*(BAMT) results in employees. Risk categories, now simplified in the 2005 CDC guidelines (low risk, medium risk, and potential ongoing transmission), can be assigned to individual areas of the facility using criteria listed in Table 95-4. A low-risk assignment can be applied to settings in which persons with TB are not expected to be encountered or to areas in which patients are not seen (e.g., administrative areas). In addition, a medium-risk category can be assigned to persons in settings who will be exposed to persons with TB or clinical specimens that might contain MTB. The new classification of potential ongoing transmission should be applied to any setting (or group of HCP) if evidence of person-to-person transmission of MTB has occurred during the preceding year. These risk categories also define what screening procedures should apply to HCP in each setting.[10] If there is difficulty in classifying a setting as low or medium risk, the setting should be classified as medium risk.

Administrative Controls

Administrative controls consist of the policies and procedures used to identify patients with potential TB as rapidly as possible so that they may be appropriately isolated and other controls initiated. Administrative controls are the most important part of a TB control plan, because other controls rely on appropriate identification of pulmonary TB patients.

In healthcare facilities at low risk that do not admit patients with TB, plans should include methods for identifying patients who may potentially have TB, mechanisms for appropriately isolating the patient while arrangements for transfer are being made, and applying a surgical mask to the patient.

In healthcare facilities that do admit patients with TB, administrative plans should include methods for identifying patients with possible TB. This may include the radiology department notifying the infection preventionist of all suspicious CXR and the microbiology lab providing notification of patients on whom an AFB stain and culture have been ordered. Some institutions automatically isolate all patients with HIV (and other high-risk patients) who have any pulmonary infiltrate and/or signs or symptoms of pulmonary disease until MTB can be ruled out.

The emergency room and clinic areas should have plans for appropriately isolating patients being seen as outpatients. These plans should include details on placing the patient in a separate area from other patients and placing a surgical mask on him or her until appropriate isolation can be arranged. The admissions office should know where appropriate airborne infection isolation (AII) rooms are within the

facility.[76]HCP should be educated on appropriate isolation techniques (also see **29. Isolation Precautions (Transmission-based Precautions)**, and **114 Heating, Ventilation, and Air Conditioning**).

Table 95-4. Risk Classifications for Healthcare Settings That Serve Communities with High Incidence of TB and Recommended Frequency of Screening for MTB Infection among Healthcare Personnel*[10]

Table 95-4 Risk Classifications for Healthcare Settings That Serve Communities with High Incidence of TB and Recommended Frequency of Screening for MTB Infection among Healthcare Personnel*

	Risk Classification†		
Setting	Low Risk	Medium Risk	Potential Ongoing Transmission‡
Inpatient <200 beds	<3 TB patients/year	≥3 TB patients/year	Evidence of ongoing MTB transmission, regardless of setting
Inpatient ≥200 beds	<6 TB patients/year	≥6 TB patients/year	Evidence of ongoing MTB transmission, regardless of setting
Outpatient and nontraditional facility-based	<3 TB patients/year	≥3 TB patients/year	Evidence of ongoing MTB transmission, regardless of setting
TB treatment facilities	Setting in which • Persons who will be treated have been demonstrated to have LTBI and not TB • A system is in place to promptly detect and triage persons who have signs or symptoms of TB to a setting in which persons with TB are treated • No cough-inducing or aerosol-generating procedures are performed	Settings in which • Persons with TB are encountered • Criteria for low risk is not otherwise met	Evidence of ongoing MTB transmission, regardless of setting
Laboratories	Laboratories in which clinical specimens that might contain MTB are not manipulated	Laboratories in which clinical specimens that might contain MTB are manipulated	Evidence of ongoing MTB transmission, regardless of setting
Recommendations for Screening Frequency			
Baseline two-step TST or one IGRA§	Yes, for all HCP upon hire	Yes, for all HCP upon hire	Yes, for all HCP upon hire
Serial TST or IGRA screening of HCP	No**	Every 12 months††	As needed in the investigation of potential ongoing transmission§§

TST or IGRA for HCP upon unprotected exposure to *MTB*	Perform a contact investigation (i.e., administer one TST as soon as possible at the time of exposure, and, if the TST result is negative, place another TST 8–10 weeks after the end of exposure to *MTB*)¶¶

*HCP refers to all paid and unpaid persons working in healthcare settings who have the potential for exposure to MTB through air space shared with persons with TB.

†Settings that serve communities with a high incidence of TB or that treat populations at high risk (e.g., those with HIV infection or other immunocompromising conditions) or that treat patients with drug-resistant TB might need to be classified as medium risk, even if they meet the low-risk criteria.

‡A classification of potential ongoing transmission should be applied to a specific group of HCP or to a specific area of the healthcare setting in which evidence of ongoing transmission is apparent, if such a group or area can be identified. Otherwise, a classification of potential ongoing transmission should be applied to the entire setting. This classification should be temporary and warrants immediate investigation and corrective steps after a determination has been made that ongoing transmission has ceased. The setting should be reclassified as medium risk, and the recommended time frame for this medium risk classification is at least 1 year.

§All HCP should have a baseline two-step TST or one IGRA result at each new healthcare setting, even if the setting is determined to be low risk. In certain settings, a choice might be made to not perform baseline TB screening or serial TB screening for HCP who (1) will never be in contact with or have shared air space with patients who have TB (e.g., telephone operators who work in a separate building from patients) or (2) will never be in contact with clinical specimens that might contain MTB. Establishment of a reliable baseline result can be beneficial

if subsequent screening is needed after an unexpected exposure to MTB.

**HCP whose duties do not include contact with patients or TB specimens do not need to be included in the serial TB screening program.

††The frequency of testing for infection with MTB will be determined by the risk assessment for the setting.

§§During an investigation of potential ongoing transmission of MTB, testing for MTB infection should be performed every 8 to 10 weeks until lapses in infection controls have been corrected and no further evidence of ongoing transmission is apparent.

¶¶Procedures for contact investigations should not be confused with two-step TST, which is used for newly hired HCP.

Once the decision to place the patient in AII has been made, patient and family education is important. The patient should understand why isolation measures are required. Even if the patient is in an appropriate isolation room, he or she should be instructed to cover the mouth with a tissue when coughing to minimize the number of organisms released into the air. Patient transport should be limited. If the patient must leave the room, he or she should be instructed to wear a surgical mask. Surgical masks were designed to prevent the spread of particles from the wearer into the air, and so they are appropriate for use in this situation.

Patients with suspected TB may be released from AII once TB has been adequately excluded as a possible diagnosis. The decision depends in part on the clinical suspicion for TB. If there is low clinical suspicion (but still enough to do an evaluation), the patient may be moved from AII once three sputum samples are negative for AFB on smear. If, however, there is a high clinical suspicion for TB, the patient must remain in isolation even if three sputum samples are AFB smear negative. The patient may have AII discontinued if an alternative diagnosis is found and TB ruled out.

Isolation for hospitalized patients with pulmonary TB may be discontinued when the patient has been on the appropriate treatment for at least 2 weeks, has had a good clinical response (e.g., resolution of fevers and cough), and has had three consecutive negative AFB smears. Some institutions require longer than 2 weeks of therapy.

Environmental Controls

Preventing the flow of infectious airborne particles from the patient's room by the use of negative-pressure ventilation and reducing the concentration of airborne particles by means of frequent air exchanges are cornerstones of TB engineering control. All rooms for TB patients should be at negative pressure relative to the hallway, so that air flows from the hall into the room. A minimum of 6 to 12 air exchanges an hour is recommended to reduce the concentration of infectious airborne particles; new

facilities should provide at least 12 air exchanges per hour. The air from an AII room should be directly vented outside in a location that prevents it from re-entering the facility's ventilation system. If recirculation of the air is unavoidable, then the air must be filtered through a high-efficiency particulate air (HEPA) filter to remove droplet nuclei before the air re-enters the main ventilation system. The door to the patient's room should be kept closed at all times to maintain proper negative pressure and airflow. The AII room should have an automatic door closer installed and a permanent visual monitoring system to ensure that negative pressure is maintained.[76](Also see **114. Heating, Ventilation, and Air Conditioning**.)

The TB control plan should provide for daily monitoring for room(s) used for AII in patients with known or suspected TB. Regular (monthly) inspection and testing of all AII rooms to verify and document proper negative pressure, so the rooms are always ready to receive TB patients. The admissions office and infection prevention should be notified of rooms that fail testing so that they will not be used until repairs are made. Changes in the facility's ventilation system should be made in consultation with the infection preventionist to ensure that the need for AII rooms is met.[76]

Ultraviolet germicidal irradiation (UVGI) may be used as an adjunct to negative-pressure ventilation and high airflows. UVGI is bactericidal for MTB, but proper placement is critical for its effectiveness.[76,77,78]

Concerns over the use of UV lights include the possibility for sunburn, skin cancers, and cataracts in HCP with frequent exposure to the lights. If UV lights are in place, they must be monitored and maintained appropriately to ensure the safety of the patient and HCP. UV lighting alone is not acceptable to control airborne spread of MTB[10](also see **114. Heating, Ventilation, and Air Conditioning**).

Personal Respiratory Protection

Personal respiratory protection consists of wearing a respirator or other protective device to prevent the inhalation of infectious droplet nuclei. Currently the U.S. Occupational Safety and Health Administration (OSHA) has mandated that HCP who may be exposed to TB must wear respiratory protection that meets at a minimum the N95 rating. In some settings with a higher than usual risk of inhaling infectious particles, a more protective respirator may be used. HCP should don the respirator. Fit testing should be performed to ensure a tight facial seal before entering the AII room. HCP should not remove the respiratory protection until they are outside of the AII room.

HCP must be trained in proper use, handling, and storage of the respirator and fit tested to ensure that the respirator provides an adequate face seal so that inhaled air comes through the filter rather than around the sides. Annual fit testing is mandatory under OSHA regulations[79]and recommended in current CDC guidelines for preventing transmission of TB.[10]Annual fit testing can also serve as an effective training tool when included in infection prevention training for HCP. The healthcare facility should purchase several types and sizes of N95 respirators so that a seal can be achieved for a variety of face types.

If an employee cannot be properly fit tested with an N95 respirator, he or she may use alternative respiratory protection such as a powered air purifying respirator with an appropriate particulate filter.

INTRAFACILITY MOVEMENT OF TUBERCULOSIS PATIENTS

Operating Room

Elective procedures on patients with known or suspected TB should be deferred until the patient can be removed from AII, either because TB was ruled out or because the patient has been treated and otherwise meets criteria established by the healthcare facility.

If a procedure cannot be delayed, an effort must be made to minimize the risk of transmission to HCP in the operating room (OR).[80]The surgical procedure should be the last of the day, if possible, to minimize the number of HCP in the area. If possible, the patient should be intubated in an AII room and brought directly to the OR—not permitted to linger in a preoperative holding area. An antibacterial filter should be placed on the endotracheal tube or at the expiratory side of the ventilator circuit. OR personnel should wear N95 respirators. (*Note*: Respirators with an exhalation valve or under positive pressure do not protect the sterile field; special N95 surgical masks are commercially available.) Ideally, the patient should be taken to an AII room before being extubated. If this is not possible, the patient may recover in the OR. A portable HEPA filter may be used in the OR during intubation and extubation to supplement air cleaning but should not be used during surgery.[80]If the patient is intubated or extubated in the OR, the doors may not be opened until the amount of time required to remove 99 percent of airborne contaminants is reached.[10]To promote airflow through the in-room air exhausts, some facilities may place damp towels along the bottoms of the room doors to minimize airflow outside the OR. (Also refer to **114. Heating, Ventilation, and Air Conditioning**for discussion of an alternative method reported for managing TB patients in the OR setting.)

Other Areas

Patients with known or suspected TB should be confined to AII rooms to the extent possible. In the event that some test or procedure must be done, the patient should wear a surgical mask when outside the room. An N95 respirator is acceptable, but masks with exhaust valves must not be used as alternatives. Because surgical masks are intended as exhalation filters, they can prevent aerosolizing infectious particles into the air. If the patient is continuously wearing a surgical mask, HCP in the area may not need to wear N95 respirators. However, because the patient's proper use of the mask cannot be guaranteed, respirators should be considered for HCP in the procedure and test areas.

ROUTINE EMPLOYEE TB SKIN TESTING

Initial Testing on Employment

It is important that all HCP have a TST or IGRA on employment to establish a baseline with which subsequent tests can be compared. This will prevent mislabeling a positive test after a TB exposure as a skin test conversion. A baseline TST (or IGRA) should be completed regardless of history of BCG vaccination because the interpretation of the test and subsequent management are not affected.

Newly hired HCP who have a history of a positive TST or IGRA should provide written proof of their result for appropriate documentation and follow-up. If an employee has had a positive test, the occupational health record should note whether he or she been appropriately screened for active TB, what the CXR results were, and whether treatment of LTBI was completed. Additionally, the test-positive HCP should be educated regarding symptoms of active disease and how, when, and where to report symptoms if they develop.

The TST should administered and read by properly trained personnel. HCP should not be allowed to read their own TST. Errors in collecting and transporting blood specimens or in running and interpreting the assay can decrease the accuracy of BAMT.[10]

HCP with a negative initial TST and who do not have documentation of a previous negative within the prior 12 months should receive a second TST (two-step) at least 1 week later to assess for the booster phenomenon. The booster phenomenon occurs because a person's reaction to tuberculin PPD can wane with time, and therefore the initial TST may be negative. The tuberculin, however, serves as a stimulus for the person's immune response, in a sense reminding it that it has seen TB antigens before. When a second TST is placed, it is subsequently positive because of the earlier reminder to the immune system. Note that serial tests with PPD alone will not induce a positive response to subsequent tests if the recipient has not been infected with TB. Unlike TST, IGRA requires a single visit for a test, as no booster phenomenon is needed for an accurate result.

RECURRENT HEALTHCARE PERSONNEL TESTING

The need for and frequency of routine recurrent TST or IGRA depend on the risk to the HCP in a given area at a given healthcare facility. Low-risk settings may perform TST or IGRA only at the time of hire and may choose not to do recurrent testing. Medium-risk settings may perform annual testing of all HCP who work in certain areas of the facility. HCP in settings classified as potential ongoing transmission, need to be tested for infection every 8 to 10 weeks with either IGRA or TST, until lapses in infection prevention have been corrected and no additional evidence of ongoing transmission is apparent.[10]Once

it is determined that ongoing transmission has ceased, the setting should be reclassified as medium risk. The latest CDC guidelines, as well as federal, state, and local regulations, should be incorporated into the healthcare facility's policy; some settings or locales may still require annual or more frequent testing of HCP, regardless of risk classification.

MANAGEMENT OF HEALTHCARE PERSONNEL WITH POSITIVE SKIN TESTS OR BLOOD ASSAY FOR *MYCOBACTERIUM TUBERCULOSIS*

All HCP who have a positive TST or IGRA should be evaluated the same as anyone with a positive test, as outlined in the section on LTBI. Ideally, an occupational health professional (physician or experienced nurse) should make this evaluation. The healthcare facility should provide INH to HCP if treatment of LTBI is indicated. This will promote compliance and reduce the risk of active TB in the future, thus reducing the risk of TB for patients and other HCP. The healthcare facility may be able to obtain a supply of INH from the local health department to use in such situations. If the facility's occupational health clinic has started the employee on INH or other treatment of LTBI, adequate follow-up should be provided.

HCP who have had a positive TST or IGRA do not need further testing, as these do not provide any useful additional information. Instead, at the time of annual testing, all HCP with a history of a positive test (whether or not treatment of LTBI was completed) should complete a questionnaire to ensure that they are not experiencing common symptoms of TB (e.g., persistent cough, weight loss, fevers, night sweats). A positive answer to any question should prompt further evaluation. The HCP should also be reminded to notify occupational health and their private physicians if any of these symptoms occur in the future.

MANAGEMENT OF HEALTHCARE EXPOSURES

Identification of Those Exposed

Occasionally TB is diagnosed in a patient in whom it was not initially suspected, and thus the patient was not placed into AII. When this occurs, patients, HCP, and visitors may have been exposed to TB, so

an epidemiological investigation should take place. Consultation with the local health jurisdiction is prudent at this point.

The first step in an exposure investigation is to establish the infectious period. A patient with evidence of lung or laryngeal disease should be assumed to be potentially infectious, even if expectorated sputum samples were AFB smear negative.[10] If TB was diagnosed from a nonrespiratory site, the patient should have a CXR, symptom review, and sputum analysis for AFB stains to determine if he or she also has pulmonary TB. If the patient has no evidence of pulmonary disease by radiograph and symptom review, and the sputum samples show no AFB, the patient is not likely to spread disease by the airborne route and AII need not be continued. No investigation of others will be needed. The exception will be for patients who have had procedures that may aerosolize TB from extrapulmonary sources (e.g., irrigation and debridement of a TB soft tissue infection, performance of an autopsy).

A concentric circle approach may be used to identify close contacts of the patient while hospitalized or in other healthcare settings. If the patient is thought to be infectious, a list should be developed of all close contacts (people with prolonged exposure time) such as roommates, direct care providers, and visitors who might have been exposed to the source patient. This may be difficult for individuals not documented in the medical record (patient chart), such as student nurses, medical students, volunteers, and others (some of whom may not be employees). Developing a list of other patients who may have been exposed in common areas, such as radiology waiting rooms, may also be problematic or even impossible. The positivity rate of skin test or IGRA results among close contacts will determine the need to expand the investigation to those contacts with less exposure. The effort that should be put into such an undertaking will depend in part on how infectious the patient is determined to be.

Tuberculin Skin Test or Blood Assay for MTB of Tuberculosis Contacts

Testing of all persons potentially exposed to the source patient is usually unnecessary. Patients who shared a room with the source patient and HCP who had the most frequent or extensive contact (e.g., nurses, physicians, others who spent more than brief moments in the room) should have a TST or BAMT as soon as possible, ideally within 2 weeks of exposure, to establish baseline results (i.e., to ensure that these persons do not already have a positive TST or BAMT assay for any reason). Visitors and patients who have already been discharged from the healthcare facility should be referred to the local health department for testing.

After initial testing, exposed patients and HCP should be retested in 8 to 10 weeks.[10] If the patients and HCP with the greatest degree of exposure have any skin test conversions or positive BAMT results, then patients, visitors, and HCP with lesser degrees of exposure should be tested (potentially in groups based on degree of exposure). Once a group shows no positive results, groups of patients, HCP, and visitors with lesser degrees of exposure need not be tested.

Assessment of Tuberculosis Control Plan

If a facility discovers that a patient with TB was not initially placed in AII, it should review the patient's chart immediately and assess the healthcare facility's administrative controls to determine how the lapse could have been prevented.

If the patient met criteria but was not isolated, the reasons should be determined and appropriate corrective measures should be documented and implemented. Measures may include additional education and training for HCP.

Part of the assessment may examine why the patient did not meet the healthcare facility's established criteria for AII.

TUBERCULOSIS CONTROL IN LONG-TERM CARE FACILITIES

TB occurs with higher than expected frequency in the elderly and may be disproportionately represented in long-term care facilities (LTCFs).[81,82] This may be a result of reactivation of latent infection or to new infection acquired from other residents with active TB. Like other healthcare settings, LTCFs should have TB control plans and AII capabilities if they accept patients with suspected or confirmed infectious TB. These plans should take into account the level of TB in their local community. At a minimum, residents and HCPs should receive two-step TST or BAMT on admission or at hire. Induration of 10 mm or more is considered a positive test for LTCF residents (unless they meet criteria for ≥5 mm).[31] The decision to treat should be based on established guidelines. Although there are concerns about development of INH hepatitis in the elderly, the 1999 ATS guidelines does not include any age limits on treatment of LTBI of unknown duration.[31] The Society for Healthcare Epidemiology of America published comprehensive guidelines for TB control in LTCFs in 2004.[82]

STATE TUBERCULOSIS CONTROL

All states have laws requiring certain HCP and healthcare entities to report proven and suspected cases of TB (active disease and possibly latent infection) to state or local health departments. Responsibility for reporting, the time frame for reporting, and the information that must be included in the report varies by state. Hospitals and other healthcare facilities should ensure that appropriate personnel are designated for reporting suspect and confirmed TB to the appropriate authorities in a timely manner.

AREAS OF CONTROVERSY AND RAPID CHANGE

Some healthcare facilities have negative-pressure operating rooms (or rooms that can be converted to negative pressure) for use with patients with active TB or other airborne-spread infections. Although such rooms may reduce the risk of MTB transmission to others, the individual patient may be put at some increased risk for a surgical site infection. There are currently no data on the extent of this risk or the extent of the risk of spread of airborne pathogens from the OR if currently recommended precautions are followed. This issue is not addressed in the CDC environmental guidelines[80]; thus, no general guidance can be given. On theoretical grounds, the benefit to both the individual patient and others would be derived from an OR that had an anteroom. The anteroom could be negative pressure to both the OR and the outside corridor, thus providing the patient the benefit of a positive pressure OR while providing the appropriate pressure relationship to the corridor to protect HCP and other patients. (See **114. Heating, Ventilation, and Air Conditioning** for discussion about an alternative method for management of a TB patient in the OR.)

Nontuberculous Mycobacteria

EPIDEMIOLOGY

Nontuberculous mycobacteria (NTM) are widely distributed through the world and can be found on soil and water. There is no evidence of human-to-human NTM transmission. Infection usually occurs from environmental sources, though sources are difficult to characterize. Asymptomatic infection is common, and skin testing studies in areas of low TB prevalence have shown that exposure starts at a young age

and peaks around age 12. The rate of infection by NTM is between 1 and 1.8 per 100,000 in industrialized nations. In the United States, the most common NTM is *M. avium*complex (MAC). The most common site of isolation is the lungs, but skin and soft tissue infection, lymph node involvement, and bloodstream infection have been reported. Disseminated disease has also been reported in immunosuppressed patients. Disseminated disease tend to occur in patients with AIDS and CD4 counts <50 cells/mm3, and in patients with interferon-γ deficiency.[83]

NTM are found readily in the environment. They may transiently colonize the airway or skin when acquired from an environmental source and only rarely cause disease. The exception may be leprosy, but skin-to-skin contact is not thought to be the major infectious pathway, contrary to centuries of belief.[84]

MICROBIOLOGY OF NONTUBERCULOUS MYCOBACTERIA

The taxonomy of NTM is an expanding field. The 1997 ATS guidelines reported 50 species; the 2007 IDSA/ATS guidelines describe 125 species. This was in part due to the availability and adoption of DNA sequencing (in particular, sequencing the gene for the 16S ribosomal RNA [16S rRBA], which is highly conserved, and a difference in less than 1 percent in its sequence is compatible with a new species). This expansion is due to the improved identification of new species, not due to the surge in new clinical entities orspecies.[83]

Like all mycobacteria, NTM are acid-fast, aerobic, Gram-positive rods (though they may not stain well with the Gram stain). The Runyon classification system is a method that classifies NTM into one of four groups on the basis of growth rates, pigmentation, and colony morphology. With newer broth culture techniques, however, even mycobacteria traditionally considered slow growers, like MTB or *M. avium*, can be grown relatively quickly. Fluorochrome stain is the preferred method of staining of samples to detect NTM, although the Ziehl–Neelsen or Kinyoun stain are less sensitive alternatives.

To enhance diagnosis and detection of NTM, current guidelines recommend performing cultures on both liquid media and solid media. They also recommend using supplemental culture media and lower temperatures for the culture of synovial fluid, bone, and soft tissue (to aid in diagnosis of more fastidious NTM, such as *M. haemophilum*and *M. marinum*; *M. haemophilum*also requires iron supplementation).

CLINICAL FEATURES

MAC is the leading cause of NTM disease in the United States and many other countries. NTM disease is most easily classified by site.

Pulmonary Disease

Pulmonary disease is the most common clinical presentation of NTM infection. MAC, *M. kansasii, M. abscessus,*and *M. fortuitum*are the most common etiological agents in NTM pulmonary disease in the United States; less frequent are *M. xenopi, M. malmoense, M. szulgai, M. simiae*, and others. MAC is the leading NTM causing pulmonary disease. The second most common organism varies by country and region.[83]

NTM pulmonary disease presents with cough, with or without fever, weight loss, hemoptysis, and progressive dyspnea. Usually symptoms are nonspecific, and imaging can show fibrocavitary of showing nodules and bronchiectasis. Because the infection occurs primarily in patients with prior pulmonary

pathology (i.e., chronic obstructive pulmonary disease, bronchiectasis), it is sometimes difficult to make a clinical diagnosis of pulmonary NTM disease.[83]

A hypersensitivity syndrome associated with exposure to indoor hot water reservoirs (tub lung) has also been described. This is characterized by a hypersensitivity reaction to aerosols, usually from warm/hot water sources colonized with MAC. Patients affected are usually younger and present with dyspnea, cough, and fever. Sometimes the hypersensitivity pneumonitis may be severe, leading to respiratory failure. *M. immunogenum*has been identified as a possible cause of this clinical syndrome in machinists with occupational exposure to metalgrinding fluids. Therapy usually involves steroids and possibly antimycobacterial medications for a short period of time and avoidance of exposures.[83]

Disseminated Disease

Disseminated disease usually occurs in patients with AIDS, and most cases are due to MAC. Other NTM like *M. kansasii*and, less frequently *M. fortuitum*, *M. scrofulaceum*, *M. gordonae*, *M. haemophilum*, *M. genavense*, *M. marinum*, *M. xenopi*, *M. malmoense*, *M. celatum,*and *M. simiae*can cause disease in AIDS patients. Dissemination is extremely rare in nonHIV infected patients, but it has been reported in patients with renal disease or leukemia, patients who have received cardiac transplants and patients receiving therapy with high-dose corticosteroids.[83]

Clinical presentation of disseminated NTM may be nonspecific, and symptoms include fever, night sweats, weight loss, abdominal pain, and occasionally diarrhea. Patients may have hepatosplenomegaly and lymphadenopathy. Anemia is common, as is elevated alkaline phosphatase and lactate dehydrogenase. In AIDS patients, disseminated MAC presents as fever of unknown origin, and disseminated *M. kansasii*, *M. chelonae*, *M. abscessus*, and *M. haemophilum*present with multiple subcutaneous nodules or abscesses.[83]

Skin and Soft Tissue Infection

Although virtually all the NTM have been described to cause cutaneous infections, *M. fortuitum, M. marinum, M. chelonea, M. abscessus*, and *M. ulcerans*are the most common. There may be a history of a puncture (e.g., stepping on a nail) or other traumatic injury.

*M. marinum*causes cutaneous lesions after exposure to swimming pools, fish tanks, or other water sources. The organisms may enter through previously unappreciated superficial nicks and abrasions. The lesions first appear as papules that later ulcerate. Because special culture conditions must be used to isolate the organism, the microbiology lab should be alerted if this is a diagnostic consideration.

*M. leprae*is the cause of leprosy (Hansen disease). This is a chronic skin infection with prominent neurological involvement. Much of the damage is a result of the peripheral neuropathy, so patients are unaware of harm being done to their tissues. *M. leprae*is not highly contagious, and only standard precautions are needed when dealing with a patient who has leprosy.

In addition to cutaneous disease, deeper abscesses, tenosynovitis, septic arthritis, bursitis, and osteomyelitis have all been described in patients with NTM.

Lymphadenitis

Lymphadenitis occurs primarily in young children. The cervical, submandibular, maxillary, and supraclavicular nodes are the most common sites of presentation. The nodes may enlarge to the point

that they drain spontaneously, but systemic symptoms are usually absent. MAC is the most common cause. The second most common cause varies by country. In adults, disease occurs almost exclusively in persons with HIV.

LABORATORY DIAGNOSIS AND PROCEDURES

Diagnosis of Pulmonary Disease

Because atypical mycobacteria may colonize the airway transiently in an immunocompetent host, the growth of such an organism is not necessarily indicative of infection. The IDSA/ATS guidelines require the presence of clinical criteria (symptoms compatible with NTM pulmonary disease, radiological changes, AND exclusion of other diagnosis) and microbiological criteria (isolation of NTM in multiple sputum cultures, or at least one BAL or biopsy). Even following these criteria, when unusual low virulence organisms like *M. gordonae*are isolated, expert consultation is recommended.[83]

Diagnosis at Other Sites

The growth of a mycobacterium from a skin biopsy or a normally sterile body site can establish the diagnosis of NTM infection. Because some species (e.g., *M. marinum*) require special culture conditions for optimal growth, the microbiology lab should be notified if an NTM infection is suspected so that the appropriate cultures will be done.

Common Confirmatory Tests

Phenotypic testing based on growth rate, pigmentation, and biochemical tests has been employed for identification of NTM in the past. Rapid-growing NTM develop within 7 days of culture (usually *M. fortuitum, M. abscessus, M. chelonae*), and can be further identified based on their pigmentation on culture media. Alternatively, high-performance liquid chromatography can be a rapid and efficient way to identify NTM. However, this test has some limitations (i.e., it has problems identifying species in the *M. simiae*complex). DNA probes have been developed and can be very useful to speciate NTM when they grow in cultures (available for several mycobacterium such as MAC, *M. kansasii*, and *M. gordonae*). Finally DNA sequence analysis of the 16S rRNA gene can be used for an accurate identification to the species level.[83]

TREATMENT STRATEGIES

The therapy of NTM can be difficult because not all anti-TB drugs are effective. As with TB, multiple drug regimens are used to treat NTM. The specific drugs used depend on the species of mycobacterium and are best chosen in consultation with someone experienced in treating such infections. Most NTM infections respond well to treatment but may require prolonged therapy.

INFECTION PREVENTION AND CONTROL MEASURES

Healthcare-associated infections (HAIs) caused by NTM are being increasingly identified. Outbreaks and sporadic reports of infections caused by NTM in the United States have a strong geographic relationship to the Gulf Coast and southeastern states. NTM are ubiquitous, and the physiopathology of infection is not entirely clear, making infection prevention challenging. Reservoirs in the environment, host susceptibility and characteristics, and mechanisms of infection have not been entirely characterized. However, there are two instances where there is a clear link with healthcare-associated transmission: skin and soft tissue infections and hypersensitivity lung disease from indoor water sources.[83]

Tap water has been a common source for many outbreaks, and some NTM are almost exclusively isolated from municipal water sources (*M. kansasii, M. xenopi*, and *M. simiae*). Several NTM like MAC can survive at high water temperatures in hospital water systems. While colonizing water systems, NTM produce biofilms that allow them to survive despite high water flow rates, which makes elimination challenging.[83]

Surgical Site Infections

NTM surgical site infections (SSIs) have been described after cardiothoracic surgery,[85,86]augmentation mammoplasty,[87,88]rhinoplasty,[89]and other surgeries. In most cases the source of the infection was exposure to tap water or a contaminated fluid.[83]In one outbreak, contaminated gentian violet used to mark the patient was identified as the source.[88]In an outbreak of NTM abdominal wound SSIs, the lubricant used for the laparoscopes proved to be the reservoir.[90]

Postinjection Abscesses

A number of sporadic cases, as well as outbreaks of localized cutaneous abscesses, have been reported that were traced to injections with contaminated needles. Unlike other healthcare-associated diseases, epidemic postinjection abscesses are most often caused by *M. chelonae*,[91,92]though outbreaks involving *M. fortuitum*and *M. abscessus*have also been reported.[93,94]

Dialysis-associated Infections

Several hemodialysis outbreaks have been reported due to contamination of the water used in dialysis.[90,95,96]Mycobacteria have been reported to cause peritonitis in patients on peritoneal dialysis.[97]NTM accounts for less than 3 percent of these reported infections; however, NTM may be a more common cause and are simply underdiagnosed.

Catheter-associated Infections

Catheter-associated infections are currently the most common HAI caused by NTM.[83,90,98]Optimal treatment requires removal of the catheter (intravascular or urinary) and administration of antibiotic therapy.

Infections Related to Implanted Devices

NTM infections have occurred with prosthetic hips, prosthetic knees, pacemakers, defibrillators, and myringotomy tubes.[90]Most cases have been sporadic.

Pseudoinfection and Pseudo-outbreaks

Numerous pseudoinfections and pseudo-outbreaks with NTM have been reported. This has often been linked to inappropriately cleaned bronchoscopes and endoscopes or contaminated endoscope washers.[99,100,101,102]Contaminated hospital water supplies and ice machines have also led to direct culture contamination or patient colonization with NTM.[101,103,104,105]Contaminated laboratory equipment and culture cross-contamination have also been reported.[106,107,108]

PREVENTION AND CONTROL OF NONTUBERCULOUS MYCOBACTERIA INFECTIONS

Surveillance plays an important role in early recognition and identification of outbreaks and pseudo-outbreaks caused by NTM. Because NTM infections may be difficult to diagnose, the recovery of a single NTM isolate from a surgical patient, dialysis patient, or sterile site should prompt further investigation to ensure that additional cases have not gone unrecognized. NTM obtained from a bronchoscopy specimen is less likely to represent an HAI but may still warrant at least a chart review. Because NTM are not typically spread person-to-person, there is no need to follow anything other than Standard Precautions.

If an NTM is identified, a review of the patient's medical records should be performed to determine whether the patient is truly infected and to obtain demographic and medical information. If the occurrence appears to be an HAI, a case definition should be made and microbiology and pathology records reviewed to find additional cases. A case-control investigation may be useful. The laboratory should be notified to save all isolates so that case and environmental isolates may be compared using molecular typing. Investigations should focus on essential issues that have already been described, including the relationship of NTM to tap and distilled water, ice, and improperly or inadequately disinfected or sterilized instruments. Policies and procedures for obtaining and processing specimens and disinfecting implicated equipment should be reviewed. Written policies and procedures may be adequate; however, witnessing the actual performance of the procedure may show the execution was not adequate. Selected environmental cultures may be useful to delineate the source of the contamination (also see **12. Outbreak Investigations**).

HCPs who work in areas that have immunosuppressed, high-risk patients or who perform diagnostic or therapeutic procedures requiring high-level disinfection of instruments should receive education about the relationship between NTM and water, the role of NTM as potential pathogens, and appropriate disinfection procedures. Personnel using glutaraldehyde or other high-level disinfectants must monitor disinfectant concentrations, the duration of disinfectant activity after activation, and the immersion time required (also see **31. Cleaning, Disinfection, and Sterilization**). Active surveillance, periodic review of cleansing and disinfection of equipment, and use of only sterile water to rinse critical and semicritical items are recommended measures to prevent pseudo-outbreaks from NTM. Use of tap water for processing bronchoscopes should be avoided. This may led to pseudo-outbreaks.[83]Use of in-line filters may help reduce water contamination. Ice should be considered potentially contaminated, and its use should be limited in operating rooms (also see **115. Water Systems Issues and Prevention of Waterborne Infectious Diseases in Healthcare Facilities**).

Patients who have been exposed to contaminated bronchoscopes or other critical or semicritical instruments should be monitored closely for the development of disease. Use of ethylene oxide to sterilize endoscopes or other instruments between patients should eliminate contamination resulting from NTM. However, processing with ethylene oxide may be cost prohibitive and require extended time for sterilization and aeration after sterilization. Emphasis on adequate cleaning and disinfection, as opposed to routine sterilization, may be sufficient if errors are identified and corrected[78](also see **55. Endoscopy**). In addition, when collecting sputum specimens, it is important that patients not rinse with or drink tap water before an expectorated specimen is collected.[83]

HCP in dialysis units should be aware of the relationship between water and NTM.[69]It is important to be meticulous when disinfecting and reusing dialyzers, and HCP must perform careful surveillance for

infections. NTM are relatively resistant to chlorine and glutaraldehyde, and decontamination of dialyzers and dialysis machines may be difficult. Facilities should routinely collect and evaluate water cultures as a quality assurance measure in dialysis units to monitor possible contamination or colonization. Routine culturing can protect patients from potential infection by eliminating excessive water colonization. In addition, Renalin may be a less effective disinfectant than formaldehyde or glutaraldehyde, so its use must be monitored closely as well. Dialysis centers that reuse dialyzers or perform high-flux dialysis should be particularly meticulous in their disinfection practices and their surveillance (also see **39. Dialysis**).

During surgery, it is important to avoid use of tap water or ice from tap water, especially during cardiac or augmentation mammoplasty. Contact of surgical wounds with tap water should also be avoided. Patients with central lines should properly cover their central lines when taking a shower and should avoid contact of the line with tap water.[83]

Quaternary ammonia does not eliminate some NTM like *M. abscessus*and *M. chelonae*.[109]When patients receive injections, use of benzalkonium chloride to disinfect the skin should be avoided. Multidose vial use should be discouraged. Patients should be educated to avoid injection of alternative medicine or unapproved substances, given risk of contamination with NTM.[83]

Conclusions

TB infection and disease remain a global concern. Although rates of TB in the United States have decreased in recent years, it is estimated that about one-third of the world's population is infected. Diagnosis and treatment of TB are important to prevent adverse outcomes and prevent spread in healthcare settings and communities. An effective TB control plan must include infection prevention and control measures to decrease the risk of transmission in healthcare settings. MDR-TB and XDR-TB strains have emerged and are more difficult to treat. NTM can cause infections, especially in immunocompromised individuals.

Future Trends

Although aggressive control measures have resulted in decreased incidence across the globe, population growth has offset gains. Increasing antimicrobial resistance with MDR-TB and XDR-TB strains is an emerging, worldwide concern. Technology advancement and techniques may be applied to help identify outbreaks and linkage to common sources.
